The atmospheric resistance of steel to corrosion increases rapidly up to 0.25% copper and then more slowly for higher percentages. The resistance to corrosion

Fig. 3—The relation of tensile strength to Charpy impact resistance of normalized carbon steels containing 0, 1, and 2% copper.

continues to increase above 0.50% copper only if it is retained in solid solution in the ferrite. This is shown by weight losses of copper-bearing steel sheets exposed to sea air for 10 months. They are as follows:

No.	C, %	Cu, %	Weight Loss, g./sq.cm.	Treatment
1	0.041	0.018	0.01671	Box annealed
2	0.017	0.196	0.01495	Box annealed
3	0.023	0.492	0.01445	Box annealed
4	0.020	1.02	0.01563	Box annealed
5	0.020	1.02	0.01360	Box annealed; reheated to 1435°F.; air quenched.

The differences in loss of weight of specimens 4 and 5 imply that the atmospheric corrosion in the higher copper steels is accelerated only when the copper exists out of solid solution in the ferrite.

Numerous exposure tests have indicated that painted and galvanized surfaces are more durable on copper-bearing than on noncopper-bearing steels.

While it is definitely established that copper increases the resistance of iron and steel to atmospheric corrosion, the results of submerged corrosion tests are not in good agreement. The influence of copper under the latter conditions is secondary to and is masked by variations in external conditions such as oxygen concentration, mill scale, and location of tests.

In summarizing the U. S. Bureau of Standards soil corrosion investigation, Logan stated that copper bearing steel does not appear to be superior when buried in soil, perhaps because of the limited supply of oxygen.

Hot Working Properties—The reputed hot shortness in the low and medium copper containing steels does not exist. Although cracks appear on the edge and surface of steels containing as little as 0.20% copper during forging or hot rolling above 2000°F., they are caused by the intergranular penetration of copper deposited beneath the scale of copper steels. This intergranular penetration of copper and the surface cracking may be corrected by adding small amounts of nickel, by hot working below the melting temperature of the copper-rich solid solution, or by preventing the formation of scale on the steel.

The high copper steels, on the other hand, owing to the occurrence of intergranular copper-rich solid solution, may be distinctly hot short at high hot working temperatures.

Table I
Summarized Results of the A.S.T.M. Atmospheric Corrosion Tests

Location of Test	Duration of Test		Gage No.	Material		Failures to Date	
	Begun	Finished		Kind	No. of Sheets	No.	Per-centage
Pittsburgh, Pa. (Industrial)	Dec., 1916	March, 1923	22	Copper	146	123	84.4
				Noncopper	84	84	100.0
				Total	230	207	90.0

				Total	259	None	0.0

Weldability—The welding qualities of steels are not influenced by copper in amounts at least up to 0.75%. The metal deposited in the weld may be strengthened by copper.

Commercial Copper Steels—The bulk of the tonnage of copper steels falls in the group containing only a few tenths per cent copper, it being added to enhance the corrosion resistance.

There is, however, a rapidly increasing tonnage of wrought steels being made containing from about 0.3% to several per cent copper, the copper being added to effect specific changes in mechanical and physical properties other than corrosion resistance. A high strength, cheap structural steel was developed in Germany containing from 0.12-0.25% carbon, 0.3-0.5% silicon, 0.5-1.0% copper, and 0.4-0.6%

chromium. Another copper-chromium structural steel developed in England contains 0.3% carbon, 0.7-1.1% manganese, 0.7-1.1% chromium, and 0.25-0.50% copper.

Fig. 4—The changes in properties of normalized carbon steels containing 1.5% copper on precipitation hardening. The width of the bands and the direction of the arrows represent the maximum changes in properties on precipitation hardening and direction which these changes take with respect to properties of normalized steels.

Table II
Mechanical Properties of Cast Steels Containing Copper

Cu., %	Heat Treatment	Tensile Strength, psi.	Yield Strength, psi.	Elongation in 2 in., %	Reduction of Area, %	Brinell Hardness	Charpy Impact, Ft.-lb.
0	Normalized 1 hr. 1650°F.	85,500	54,500	29.5	53.4	146	21.1

2.40		119,000	93,500	19.3	44.2	223	9.3

Both steels have higher yield strengths than carbon steels of the same carbon contents and ductilities not appreciably lower than those of the carbon steels. A high

strength, corrosion resistant steel containing 0.10% carbon, 0.10-0.30% manganese, 0.10-0.20% phosphorus, from 0.50-1.0% silicon, 0.30-0.50% copper, and 0.50-1.50% chromium, recently developed here, is being used in the construction of light weight transportation equipment.

Other recently developed copper-bearing steels of the low alloy, high strength type, are as follows:

% C	% Mn	% Cu	% Ni	% Mo	% Si	% P	% Cr
0.08-0.22	1.00	2.00
0.12 max.	1.00 max.	0.5-1.5	0.5-1.0	0.20
0.12 max.	0.5-0.7	0.9-1.25	0.45-0.65	0.30 max.	0.10-0.15
0.12 max.	0.15-0.90	0.30-0.80	0.30-0.80	0.05-0.25	0.05-0.15
0.25 max.	0.75 max.	0.30-0.50	0.25 max.	0.08-0.10
0.35 max.	1.25-1.75	0.40 min.	0.30 max.	0.25 max.
0.14	0.70-0.90	0.25-0.30	0.15-0.20	0.12
0.08-0.30	0.60-0.70	0.40-0.60	0.25 max.	0.50 max.	0.25 max.

The presence of 1 or 2% copper in corrosion resistant chromium steels increases the resistance to atmospheric and salt water corrosion and to attack by certain acids. The influence, however, is not great and few of the corrosion resistant steels contain copper. A ferritic steel for resistance to atmospheric corrosion contains approximately 16% chromium, 1% silicon, 1% copper, 0.40% manganese, and under 0.1% carbon. Another for abrasion resistance contains 0.3% carbon, 20% chromium, and 1% copper. Several austenitic corrosion resistant alloys recently developed contain from 1-4% copper.

Many cast steels are alloyed with copper. The mechanical properties of steels with 0, 1.21, 1.76, and 2.40% copper and with base compositions of 0.31% carbon, 0.42% silicon, 0.75% manganese, 0.029% sulphur, and 0.034% phosphorus are given in Table II.

A heat treated cast steel crankshaft containing 1.25-1.40% carbon, 0.50-0.60% manganese, 1.90-2.10% silicon, 0.35-0.40% chromium, 2.50-2.75% copper, and 0.10% (max.) phosphorus is being used in one make of automobile.

Manganese As An Alloying Element in Pearlitic Steels

By A. Oram Fulton*

Manganese is a very hard grayish white metal, with a reddish lustre. It takes a high polish and is not malleable. When in an extremely pure state, manganese scratches glass. The article "Physical Constants of the Principal Alloy Forming Elements" in this Handbook gives the physical constants for manganese.

Historical—Manganese was first isolated in 1774 by Gahn working with Scheele. It was used as an addition to crucible steel by Heath in 1839. Mushet in 1856 patented the addition of spiegel to Bessemer steel. Mushet also developed the first so-called "high-speed" steels which contained about 2.5% manganese.

Sir Robert A. Hadfield in 1882 made a series of steels containing from 0.83-21.69% manganese. The experiments and conclusions drawn were detailed in a paper which he presented before the British Iron and Steel Institute in 1888.¹

Hadfield's conclusions resulted in a decided impetus being given to the manufacture and use of austenitic high manganese steels, but steel containing manganese in low percentages or pearlitic manganese steels were condemned as being brittle and having no practical applications.

In the light of later developments, we now know that this erroneous conclusion with regard to low manganese steels was due to the fact that Hadfield did not work

with a sufficient variety of low carbon, low manganese steels, or rather, with low manganese steels containing carbon in the proper relation to the manganese content.

In 1903 Leon Guillet reported² an extensive research on manganese steels. He examined two series of steels: First, the steels containing a small percentage of carbon (at the most 0.3%); second, the steels in the vicinity of the eutectoid ratio containing from 0.7-1% carbon.

The result of Guillet's experiments was to completely disprove the previously accepted theory that low manganese steels were brittle. Indeed Guillet went farther and added that "these steels possess a remarkable shock resistance, and especially a uniformity which is only met with exceptionally in carbon steels."

Following Guillet's experiments low manganese steels began to be manufactured commercially in this country and have had a steady development to the point where they are now meeting with exceeding favor by reason of their machinability, case hardening properties, strength and toughness.

Ores and Their Occurrence—Manganese ores are found in many parts of the world. Their occurrence in the United States may be grouped as follows:

1. Manganese ores, containing at least 35% manganese, are found most abundantly in the Appalachian and Piedmont regions of Virginia and Georgia, and on the Pacific Coast.

2. Manganiferous-iron ores, containing usually more than 5% manganese and a variable proportion of iron, are found chiefly in New England, the Appalachian region, and the Lake Superior iron district.

Fig. 1—Extra equilibrium constitution chart for condition resulting from water quench from 1740°F.

Fig. 1A—Same as Fig. 1, but free air cooled from 1740°F.

3. Manganiferous-silver ores, consisting of mixtures of manganese, iron oxides, and hydroxides with small amounts of lead and silver, are found in the Rocky Mountain and Great Basin regions, but chiefly at Leadville, Colo.

Enormous deposits of manganese ore are found in Southern Russia and Minas Geraes, Brazil.

Manganese itself has no uses but forms valuable alloys with copper, iron, zinc, tin, aluminum, lead, and magnesium. Those with iron, depending upon the percentage of manganese content, are known variously by the names spiegeleisen, ferromanganese, and silicomanganese.

Method of Adding Manganese to Steel^a

Standard Ferromanganese—Manganese is most commonly introduced into steel in the form of ferromanganese which analyzes approximately: Manganese 78-82%, iron 15-19%, carbon 6-8%, with small percentages of silicon, phosphorus, and sulphur. Frequently, in order to lower costs, ferromanganese is added in the ladle, but a much better quality of steel is produced when the ferromanganese is added in the furnace. The latter method, however, results in a greater loss of manganese.

Low Carbon Ferromanganese—In making low carbon, low manganese steel, standard ferromanganese of the above analysis, because of its carbon content, cannot be used entirely, and must be supplemented by the use of a low carbon ferromanganese. For this purpose a low carbon ferromanganese (carbon 0.3-1%, manganese 80-85%) is used, which can be added either in the ladle or furnace, preferably in the furnace.

Spiegeleisen—Spiegeleisen, which in effect is a high manganese pig iron, containing 15-30% manganese and 4.5-5% carbon, is used in Bessemer and basic open hearth practice in making high carbon steels, usually being added to the steel in molten form direct from a cupola.

Fig. 2—Physical properties of manganese steels, Type 2, Table I. Bar $\frac{3}{4}$ in. round. Quenched into water from 1650°F.

Silicomanganese—Frequently in making low carbon steel where there is no objection to silicon, silicomanganese is used. Silicomanganese analyzes: Manganese 65-70%, silicon 16-25%, and carbon either 1, 2 or 2.5% maximum as desired. It is added either in the ladle or the furnace, preferably the latter.

Effect of Manganese on Steel—Manganese when added to steel has a beneficial effect both directly and indirectly. It increases the strength of the steel directly in that the excess manganese combines with some of the carbon to form the carbide of manganese, Mn_3C , and this carbide is found associated with the iron carbide, Fe_3C , in cementite.

It has generally been held that iron and manganese form a series of solid solutions. In the light of recent research it appears that such is not the case. The solubility of manganese in iron at room temperature seems to be close to 1.6% manganese. If more than that amount is added to iron (or to steels very low in carbon) iron and manganese often display martensitic-like structures, which on exam-

^aW. J. Priestly, *Metals and Ferroalloys Used in the Manufacture of Steel*, Metals Handbook.

ination prove to be two kinds of solid solutions. In this respect iron-manganese alloys appear to be much like the alloys of iron and nickel.⁴

The indirect beneficial effect of adding manganese to steel is due to its action as a scavenger. It counteracts the effect of certain harmful oxides or gases and eliminates the harmful effect of sulphur by combining readily with it to form manganese sulphide, MnS .

The addition of manganese to steel lowers the transformation temperatures. A summary⁵ of published results obtained in studies of pearlitic manganese steels showed that the A_{c1} point is lowered $11^{\circ}F.$ for each per cent increase in manganese; the A_{c2} point is lowered $116^{\circ}F.$ for each per cent increase in manganese up to 1%, but only $6-11^{\circ}F.$ for each per cent increase in manganese up to 3%; the A_{r1} point is lowered $125^{\circ}F.$ for each per cent increase in manganese; the A_{r2} point is lowered

variably, but about $90^{\circ}F.$ for each per cent increase in manganese.

Manganese not only lowers the transformation points, but renders such transformation extremely sluggish. That is to say, the allotropic transformation does not take place at any definite temperature, but occupies a whole range of temperatures, sometimes as much as 150° . In simpler words, it may be explained that the beginning and the end of the transformation are about 150° apart, this figure depending on the amount of manganese.⁶

Fig. 3—Physical properties of manganese steel, Type 3, Table 1. The Rockwell "C" scale was used. Quenched into water from $1575-1600^{\circ}F.$ and tempered to the hardness shown.

In a study of 36 iron-carbon-manganese alloys of commercial purity limited by 1.5% carbon and 15% manganese, by E. C. Bain, E. S. Davenport, and W. S. N. Waring in a paper presented to the A.I.M.E. in Feb., 1932, the extra equilibrium constitution chart was developed for the condition resulting from water quench from $1740^{\circ}F.$, also, for the condition resulting from free air cool from $1740^{\circ}F.$ These charts are presented in Fig. 1 and 1A.

The letters used in the diagrams represent the following constituents: A, austenite; F, ferrite; C, carbide; ϵ , epsilon; M, martensite; T, troostite; P, pearlite.

Standard Manganese Steels—Table I lists the pearlitic manganese steels which are most commonly used. There are other analyses adopted by individual manufacturers and users, but the following are those having at present general distribution.

⁴Vsevolod N. Krivobok, Personal Communication.

⁵J. Straus, Medium Carbon Pearlitic Manganese Steels, Trans., A.S.S.T., 1928, v. 14, p. 2, 3.

⁶Vsevolod N. Krivobok, Personal Communication.

In the case of the steels with S.A.E. designations the term "standard" refers to the analysis range recommended by the Society of Automotive Engineers. In the case of steels without S.A.E. nomenclature the term "standard" refers to recommended analyses of individual manufacturers and users.

Table I
Composition Pearlitic Manganese Steels

Steel Type	S.A.E. No.	C	Mn	P	S
1	X-1314	0.10-0.20	1.00-1.30	0.045 max.	0.075-0.15
2	X-1315	0.10-0.20	1.30-1.60	0.045 max.	0.075-0.15
3*	0.10-0.20	1.30-1.60	0.04 max.	0.08 max.
4	X-1330	0.25-0.35	1.35-1.65	0.045 max.	0.075-0.15
5	X-1335	0.30-0.40	1.35-1.65	0.045 max.	0.075-0.15
6	X-1340	0.35-0.45	1.35-1.65	0.045 max.	0.075-0.15
7	T-1330	0.25-0.35	1.60-1.90	0.040 max.	0.050 max.
8	T-1335	0.30-0.40	1.60-1.90	0.040 max.	0.050 max.
9	T-1340	0.35-0.45	1.60-1.90	0.040 max.	0.050 max.
10	T-1345	0.40-0.50	1.60-1.90	0.040 max.	0.050 max.
11	T-1350	0.45-0.55	1.60-1.90	0.040 max.	0.050 max.
12*	0.45-0.55	1.00-1.30	0.040 max.	0.08 max.

*Types 3 and 12 are frequently furnished with additions of chromium and/or molybdenum in varying percentages.

Types 1, 4, and 3 are most commonly used for case hardened parts, such as roller bearings, camshafts, and gears. These steels harden with a hard case at low temperatures and possess a strong, tough core. They all possess superior machining qualities and are classed as free cutting steels.

Case Hardening Types 1, 2, and 3—Following are the various recommended practices for case hardening of these grades:

X-1314—I and X-1315—I

1. Carburize at 1650-1700°F.
2. Quench direct
3. Temper to 250-325°F.

X-1314—II and X-1315—II

1. Carburize at 1650-1700°F.
2. Quench direct
3. Reheat to 1400-1450°F.
4. Quench
5. Temper to 250-325°F.

X-1314—III and X-1315—III

1. Carburize at 1650-1700°F.
2. Cool slowly or in box
3. Reheat to 1400-1450°F.
4. Quench
5. Temper to 250-325°F.

X-1314—IV and X-1315—IV

1. Carburize at 1650-1700°F.
2. Cool slowly or in box
3. Reheat to 1650-1700°F.
4. Quench
5. Reheat to 1400-1450°F.
6. Quench
7. Temper to 250-325°F.

X-1314—V and X-1315—V

1. Heat to 1500-1650°F. in cyanide or activated bath
2. Quench in oil or water
3. Temper if desired

Parts "cased" in activated baths may be given refining heats as indicated in preceding heat treatments.

The particular practice selected in a specific instance depends upon a variety of factors, as, for instance, the degree of core toughness, the depth of case, the hardness of case desired, the relative importance of the part, and the cost of the operation.

The allotropic transformation in pearlitic manganese steels occupies a whole range of temperatures, sometimes as much as 150° apart. This means that these steels are sluggish in passing through the critical range. It is desirable to keep the double carbides of iron and manganese in solid solution in order to prevent brittleness. With Types 1, 2, and 3 this can be done best by quenching them direct from the pot rather than to permit the carbides to be precipitated from solid solution by cooling in the pot. When this direct quench from the pot is used, it should, of course, be followed by subsequent treatment for the refinement of the case.

Heat Treatment and Uses of Pearlitic Manganese Steels—Types 1, 2, and 3 are frequently heat treated for strength and toughness by direct quench in water without carburizing and then reheating as required. Excellent physical properties result. Fig. 2 and 3 show the physical properties of two of these steels with varying tempering temperatures or at different conditions of hardness obtained by varying heat treatments.

Types 4, 5, and 6 are classified as free cutting steels and for many purposes may be substituted for carbon steels of similar carbon content where improved machining, deeper hardening, and higher physical properties are desired. With increasing carbon, the manganese steels become primarily oil hardening and can be treated in water only by exercising great care and extreme risk of cracking.

X-1330—I

1. Heat to 1525-1575°F.
2. Quench in water or oil depending upon section
3. Temper to required hardness

X-1330—II

1. Normalize at 1650-1750°F.
2. Machine
3. Heat to 1525-1575°F.
4. Quench in water or oil depending upon section
5. Temper to required hardness

Heat Treatments**X-1335—I and X-1340—I**

1. Heat to 1500-1550°F.
2. Quench in water or oil depending upon section
3. Temper to required hardness

X-1335—II and X-1340—II

1. Normalize at 1650-1750°F.
2. Machine
3. Heat to 1500-1550°F.
4. Quench in water or oil depending upon section
5. Temper to required hardness

Types 7, 8, 9, 10, and 11 are manganese alloy steels and for many applications may be used interchangeably with other medium alloy steels of similar carbon content. They possess good physical properties and may frequently be used in place of other medium alloy steels at a saving in cost. These steels are primarily intended for oil hardening and can only be quenched in water at extreme risk. Common uses are heat treated shafts, gears, and spindles.

Steel Type 12, with additions of chromium or molybdenum, or both, is used

where high physical properties are required. Common uses are gears, shafts, clutches, and bolts. This type is invariably quenched into oil. The physical properties of this steel are shown in Fig. 6 when heat treated to the varying degrees of hardness indicated in the abscissae.

The heat treatment consists of quenching into oil from 1475-1500°F. followed by tempering to the hardness desired.

General Properties of Pearlitic Manganese Steels

Welding—These steels cannot properly be classed as "welding steels," but may be used without difficulty in the manufacture of parts which involve welding in their fabrication.

Forging—None of these steels present any unusual difficulties in any of the regular forging operations, and can be freely used in parts which require forging as a necessary preliminary to their manufacture.

Cold Drawing—Pearlitic manganese steels may be cold drawn without difficulty. Like other alloy steels, it is recommended when cold drawing steels of 0.35% carbon or more that they be annealed so as to obtain a lamellar pearlitic structure before the drawing operation.

Machining—As a class, the pearlitic manganese steels are particularly free machining.

Indeed, the low carbon steels, such as Types 1, 2, and 3 in Table I are practically equivalent in their machining properties to Bessemer screw stock. As the carbon, manganese, and any other alloying elements are increased, the machining becomes more difficult. In the case of steels of over 0.40% carbon, it is recommended that they be annealed before machining.

Other Types of Manganese Steels—Pearlitic manganese steels are made with the manganese content higher (up to 3%) than those steels described above, but have a limited and special use. Steels are made containing manganese from 1-2% in combination of varying percentages with nickel, chromium, molybdenum, silicon, and other elements. These steels likewise are limited in use and have a highly specialized application. While they possess unusually good physical properties, they have presented too many manufacturing difficulties to the user for general adoption.

Fig. 4—Physical properties of manganese steel, Type 4, Table I. Bar $\frac{1}{2}$ in. round. Quenched into oil from 1525°F.

Fig. 5—Physical properties of manganese steel, Type 5, Table I. Bar $\frac{3}{4}$ in. round. Quenched into oil from 1475°F.

The chief difficulties are that they add considerable cost in fabrication due to difficulty in the forging and machining operations.

Manganese in Tool Steel—The average "normal" manganese content in tool steel is 0.20-0.35%. One special type of manganese tool steel has very decided nonchangeable or non-deforming qualities, however, and is very generally used. The composition of this steel varies somewhat with different manufacturers. The approximate chemical composition is C 0.90-1.00% and Mn 1.00-1.50%.

Some manufacturers run the manganese as high as 1.80%, with or without vanadium, while others add 0.50% chromium, 0.50% tungsten, or about 0.25% vanadium, or combinations of these. This steel, however, depends essentially for its qualities upon the carbon and manganese content.

The heat treatment consists in quenching in oil from approximately 1450°F. followed by tempering as required, usually 325-400°F.

Fig. 6—Physical properties of manganese steel, Type 12, Table I, with Cr 0.55% and Mo 0.15%. Quenched into oil from 1475-1500°F. and tempered to the hardness shown.

Austenitic Manganese Steels

By John Howe Hall*

General—Austenitic, or Hadfield's manganese steel, was one of the first alloy steels discovered and produced on a commercial scale. The experiments of Sir Robert A. Hadfield at his father's Sheffield plant in 1882 led to the development of this alloy, which has occupied a unique place among metallurgical products for fifty years. In general, wherever hard materials are to be dug, crushed, handled, or moved, manganese steel parts are widely employed to resist the heavy wear involved in these operations, and so far no other metal has proved equal to it in a countless number of such applications.

Composition—The constitution of iron-manganese-carbon alloys is fully discussed on page 408 Metals Handbook. The useful range of composition for austenitic manganese steels does not include all the possible compositions shown in the constitution diagram of manganese steels. The valuable austenitic manganese steels are confined to those that are truly austenitic after quenching the steel in water from a temperature of 1830°F., or slightly over. This range of composition is that included between the line X—Y and W—Z in Fig. 1. The equations of these lines are approximately as follows:

$$\text{Carbon} = 1.075 + \frac{0.1 \text{ Mn}}{3} \quad \text{and}$$

$$\text{Carbon} = 1.075 - 0.04 \text{ Mn}^\dagger$$

To the right of the line WZ the steel in the quenched condition will contain considerable free carbide which reduces its strength and toughness. To the left of the line XY lie the steels that are more or less martensitic and brittle after quenching. This useful area was determined by an investigation made by the author in 1907-1908 in which a number of melts of steel were prepared, analyzed, and examined.

As not all the steels lying in the area bounded by these lines are sufficiently strong and tough for the severe service to which manganese steel is subjected, the composition (in %) of commercial austenitic manganese steels lies within the following limits:

C 1.00-1.40, Mn 10.00 (min.), Si 0.30-1.00, S 0.05 (max.), and P 0.10 (max.).

The more experienced makers set a lower limit of manganese at 11.00 instead of 10.00%, as the steels containing less than 11.00% manganese are somewhat lacking in toughness and strength.

Manufacture—The steel is made by the electric furnace, open hearth, or Bessemer process. In the case of the open hearth, Bessemer, and acid electric furnace methods, standard 80% ferromanganese is melted in crucibles, a cupola, or a small electric furnace, and is mixed in the ladle with approx. 5 times its weight of molten, low carbon steel. The latter may be tapped from an acid or basic open hearth furnace, a side-blown or small bottom-blown Bessemer converter, or an acid electric furnace. The cupola for the ferromanganese and the small converter for the low carbon steel are the preferred melting mediums for this method of manufacture. On

Fig. 1—Modified form of Guillet's diagram for manganese steels.

account of the difficulty of controlling the slag volume and composition, the cutting of the bottom, and the impossibility of keeping the loss of manganese within reasonable limits, it is not possible to add ferromanganese or manganese steel scrap to the bath in the acid electric furnace, as is done with most other alloy steels. For this reason, when the acid electric furnace is used as the melting medium, manganese steel scrap can not be remelted as a part of the charge, but must be disposed of in some other manner. When the open hearth furnace is the source of the metal, manganese steel scrap can be remelted in it, but only at the cost of the loss of practically all the manganese contained in the scrap.

Obviously, if converters are used to produce the steel base for the alloy, it is necessary to premelt the ferromanganese, as such a large amount of the latter cannot otherwise be incorporated

*Consulting Engineer, Chestnut Hill, Phila., Pa.

†John Howe Hall, J. Ind. and Eng. Chem., 1915, v. 7, No. 2, p. 94.

in the steel without chilling it too much. Premelted ferromanganese is desirable also for mixing with open hearth steel, because, if the ferromanganese were added solid to the bath in the furnace, the loss of manganese would be excessive.

When the basic electric furnace is used, the ferromanganese is added in the furnace to a charge of low carbon steel, and more or less austenitic manganese steel scrap is generally incorporated in the charge. In some shops, all of the ferromanganese is added after the bath is melted, in others a large proportion of it is included in the initial charge. This is the only steel making process by which manganese steel scrap can be remelted without almost total loss of the contained manganese. The electric furnaces used are generally of the arc type, but of late years the coreless induction furnace has come forward as a competitor in this field.

The carbon content of standard 80% ferromanganese is such that, when the proper amount is added to a bath of low carbon steel, the manganese will be within the desired limits, and the carbon will be from 1-1.40%. If the carbon is below 1%, the steel is less resistant to wear. Carbon above 1.40% is undesirable, as it increases the tendency of the steel to crack in heat treatment.

Ferromanganese ordinarily carries enough silicon to give the resultant steel at least 0.30% silicon. No appreciable effect on the physical properties can be found from variations in silicon between 0.30 and 1%. When manganese steel is made in the basic electric furnace, with manganese steel scrap as a considerable proportion of the charge, it is desirable to add more silicon than is contained in the ferromanganese. In this case, a silicon content of over 0.50% in the finished steel is desirable.

The sulphur is usually so low as to be negligible, because the manganese forms MnS with part of the sulphur present in the steel, which floats to the surface and enters the slag.

The phosphorus content is dependent upon that of the ferromanganese used. It is generally between 0.06 and 0.09%. Up to 0.1% phosphorus may be present in the steel without ascertainable harmful effect.

Heat Treatment—In the cast condition, manganese steel is quite brittle. In this condition the structure consists of austenite, with considerable free carbide in patches and in a network between the austenite crystals. To strengthen and toughen the metal, the pieces are heated to between 1830 and 1940°F. and quenched in cold water. When the composition of the steel is within the correct limits, this treatment results in all the carbide being taken into solid solution in the austenite and produces a uniform austenitic structure and a high degree of strength and toughness. When the carbon exceeds 1.40-1.50%, free cementite will be found in amounts which increase in proportion to the carbon content and which will decrease the toughness and strength of the steel. A similar effect is caused in steel of correct composition if it is heated to too low a temperature before quenching, or if it is allowed to cool off too much between the time it is taken from the furnace and the time when it is immersed in the water.

If the heat treated steel were to be reheated for a long time at 660°F., or for a shorter time at or above 750°F., it would become exceedingly brittle, due to the liberation of carbide and the partial transformation of the austenite. This makes it impossible to reheat the steel after quenching for the removal of cooling stresses, as is done with most quenched steels. These stresses are far higher than in the case of most other steels, because the heat conductivity of manganese steel is but $\frac{1}{4}$ that of iron, and its coefficient of thermal expansion is somewhat higher—about $1\frac{1}{2}$ times that of pure iron. The low thermal conductivity results in a great difference in the cooling rate between light and heavy sections, and between the inside and the outside portions of heavy sections. When the castings are quenched, great stress is produced, which is still further increased by the high coefficient of thermal expansion. As tempering is not possible to relieve these stresses, reasonable uniformity of sections between different parts of a single casting is absolutely essential to avoid severe warping and even breaking of the castings in treatment.

The same considerations limit sharply the maximum thickness of manganese steel parts that can be successfully heat treated. When attempts are made to quench sections over 5 or at the very most 6 in. thick, the stresses due to the unequal cooling rates of the inside and the outside portions of the piece are so severe as to produce cracks, and these cracks generally begin at the center of the section and extend outward. As they do not always extend to the surface, their

presence is not always detected, with the result that the piece fails in service after a comparatively short life.

Properties of Austenitic Manganese Steel—In the rolled or hammered condition the properties of heat treated austenitic, high manganese steel will usually come within the following limits:

Tensile Strength, psi.	Limit of Prop. ¹ psi.	Elongation, % in 2 in.	Reduction of Area, %	Brinell Hardness
130,000-160,000	40,000-60,000	60-70	40-60	230

¹Limit of proportionality is given because austenitic manganese steels show no well marked yield point.

In the cast condition the properties of the heat treated steel vary somewhat, depending upon the form of the specimen from which the test piece is obtained. When a tensile bar is cast approximately to size, the properties obtained from it, which undoubtedly represent those of the cross section of similar light castings, are not so high as those of pieces ground from the usual coupons used to make tests of cast steels. The latter, of course, are fairly representative of the metal in the greater part of the cross section of heavier castings.

The temperature at which manganese steel is poured has a marked effect upon the strength of the castings. A high pouring temperature produces a coarse crystalline structure which is not refined in heat treatment, and which is some 15,000-20,000 psi. lower in tensile strength than the fine grained steel obtained when it is poured at lower temperatures. Depending upon pouring temperature and the origin of the test piece, the physical properties of cast heat treated austenitic manganese steel are as follows:

Type of Specimen	Tensile Strength, psi.	Proportional Limit, psi.	Elongation, % in 2 in.
Cast to size.....	80,000-110,000	15-35
Ground from coupon.....	118,000 ^a	42,900 ^b	44.1 ^a

^aAverage of 15 tests.
^bAverage of 5 tests.

Type of Specimen	Reduction of Area, %	Brinell Hardness	Bend ½ in. x ¾ in. on 1 in. Pin, Degrees	Limit of Propor- tionality in Compression, psi.
Cast to size.....	15-35	180-220	180
Ground from coupon.....	39.0 ^a	24,000

^aAverage of 15 tests.

Type of Specimen	Shearing Strength, Single Shear, psi.	Fatigue Limit, psi.

Ground from coupon.....	39,000 ^a

^aDetermined with H. F. Moore type machine.

Electrical, Magnetic, and Thermal Properties—The electrical resistance of austenitic manganese steel is 71 microhms per cm.-cube, or 7 times that of pure iron; the average thermal conductivity between 0 and 100°C. is 0.027 cgs. units or about ¼ that of pure iron; and the mean coefficient of thermal expansion between 0 and 100°C. is 0.000018 per 1°C., or about 1½ times that of pure iron.¹

To all intents and purposes, manganese steel is nonmagnetic, that is, it has no attraction for the magnet. If a bar of the steel be placed across an ordinary field compass, the needle will be deflected only 1 or 2°. As yet very little practical use has been made of this property and for years the only application of the steel based on its nonmagnetic properties was the cover plates of electric lifting magnets, in which the power of resisting wear was also of value. Of late the attention of electrical engineers has been drawn to the subject and the steel is being applied to various transformer parts and other portions of electrical machinery where a strong, nonmagnetic metal is essential.

¹R. A. Hadfield, *Metallurgy and Its Influence on Modern Progress*, Chapman & Hall, Limited, London, 1925.

Determinations made of normal induction and magnetizing force gave results as follows:

Induction, Gausses	Magnetizing Force, Gilbert's per sq.cm.
10.....	9.5
20.....	18.4
30.....	27.3
50.....	44.8
70.....	62.5
100.....	89.3
150.....	136
200.....	183
250.....	231
300.....	279

The magnetic permeability, being the ratio of induction to magnetizing force, is nearly unity, the permeability of air, for the determinations in this table.

From Smithsonian Physical Tables, Sixth Edition, p. 321, the following figures are quoted for magnetic values in intense fields, the references given being the work of Ewing:

Magneto Motive Force	Magnetic Moment per cu.cm.	Magnetic Induction	Permeability
1930	55	2620	1.36
2380	84	3430	1.44
3350	84	4400	1.31
5920	111	7310	1.24
6620	187	8970	1.35
7890	191	10290	1.30
8390	263	11690	1.39
9810	396	14790	1.51

Hardening Power of Austenitic Manganese Steels—The Brinell hardness of the steel in the cast and in the heat treated condition is only moderately high, about 185 in the untreated condition and 180-200 after treatment. The correctness of this relatively low figure is confirmed by the fact that the steel can be dented with the peen end of a machinist's hammer, or nicked with a cold chisel, up to a certain point. The first blows of the hammer produce a considerable dent, but as the hammering proceeds the impression produced grows smaller and smaller, and finally a point is reached where the hammer hardly mars the surface, because the steel has grown much harder from the effect of the cold working. A Brinell test upon the cold worked surface shows a hardness of from 450-550, instead of the 180-200 of the heat treated steel. In fact, the rapidity with which this metal hardens under cold working of all kinds is extraordinary, and is probably responsible for its most valuable property, the ability to endure severe abrasion coupled with heavy pressure or blows.

Wear—Manganese steel owes its power of resisting heavy abrasive wear to the property of hardening under cold working to an extent approached by few other ferrous metals. The late Henry M. Howe first called attention to this phenomenon in a paper before the A.I.M.E.¹ In a jaw crusher, for instance, where the steel is subjected both to heavy pressure and severe abrasion, manganese steel will generally greatly outlast metals whose initial hardness is much greater. Tests have shown that the initial rate of wear of a manganese steel crusher jaw is somewhat greater than the rate after a few tons of stone have been crushed. This is due, of course, to the hardening of the steel by the kneading effect of the stone crushed. Jaws of other hard metals, such as nickel, chromium, and nickel-chromium steel, and chilled iron, show practically no difference in the rate of wear as the test progresses, and in consequence of their higher initial rate of wear and of the fact that this rate decreases little if any as the test progresses, jaws of these steels wear out after a life measured in terms of tons of stone crushed usually much less than that of manganese steel.

In wear of a different type, where cold working is largely absent, so that the steel is not surface hardened by the pressure, austenitic manganese steel does not

¹H. M. Howe and A. G. Levy, Are the Deformation Lines in Manganese Steel Twins or Slip Bands?, Trans., A.I.M.E., 1915, v. 51, p. 881.

outwear other metals to the same extent as in the typical case of crusher jaws. Under the action of the pure abrasion of a sand blast, for instance, chilled iron will outwear manganese steel, so that the latter does not make a satisfactory sandblast nozzle. In the many types of service where abrasion and cold working are encountered in varying proportions, the advantage of using manganese steel will depend largely upon whether there is enough pounding or pressure to produce a useful degree of hardening.

Applications of Austenitic Manganese Steels—Typical applications of cast high manganese steel are railway and trolley frogs, crossings and switches, rock crusher parts, steam shovel dippers and teeth, gold, platinum, tin, and gravel dredge buckets and lips, conveyor chain, sprockets, gears and pinions of many types, centrifugal pump parts for gravel dredges, ball and tube mill liners, rough paper making machinery, orange peel and clam shell dipper lips and points, tractor shoes and many others. Castings are furnished in all weights from a few ounces to 25,000 or even 30,000 lb. In the rolled condition the chief application is in rails used for special service, though a small amount is used for light forgings subjected to heavy wear, for woven screens, and some similar uses.

Machining—Largely because it hardens under and in front of the tool, heat treated austenitic manganese steel is machined only with great difficulty. For many years, in fact, all efforts to machine it commercially were failures, and finishing operations were universally carried out in grinding machines. Of late years some manufacturers of manganese steel have found that by using exceedingly heavy, rigid machine tools and the most modern tool steels, some machining operations can be carried out more economically than grinding. In general, steel tools are better suited to this work than the cemented carbides and similar metals, because under the heavy pressures required to cut manganese steel successfully, the more brittle metals are likely to break and spall. The great majority of the finishing work on manganese steel castings is still performed with grinding wheels.

Welding—Until comparatively recent years, gas or electric welds in manganese steel have been unsatisfactory, because the heat of the arc or torch damaged the manganese steel close to the weld, making it brittle. Periodic quenching of the weld does not prevent this brittleness, because it is due to two effects upon the metal, one of which is curable only by reheat treating the whole casting, and the other is curable only in part by any thermal or mechanical treatment.

A welding rod has recently been developed containing from 3-5% nickel and 13-15% manganese, with carbon generally from 0.60-0.80%. With this, welds in manganese steel are made which develop from 50-60% of the strength of the unwelded metal. The combined effect of the nickel and the low carbon content is to greatly strengthen and toughen the "contact zone" of manganese steel close to the weld line, in which failure occurs when welding rods of composition similar to that of the castings are used. The adoption of these low carbon-nickel-manganese steel rods has resulted in making the fusion welding of manganese steel commercially successful, and many difficult welds of worn and cracked parts are now giving satisfactory results in severe service.

Some authorities on welding prefer to use welding rods or electrodes of the 18 Cr -8 Ni type for welding cracked or broken manganese steel parts, covering the welds over with manganese steel to obtain good wear resistance in the welded area. The author's experience has been that stronger and more satisfactory welds are obtained with the nickel-manganese steel rods described above.¹

Special Compositions—Austenitic manganese steels containing varying amounts of other alloys have been made in recent years. One of these steels whose application is the welding rod described above, has been found to roll and forge more easily than manganese steel of standard analysis, and to be less easily damaged by exposure to temperatures just below dark red heat. In the form of bars, sheet, and plate it is to some extent displacing rolled products of the older Hadfield range of composition. Car bearing parts, woven screen, and similar applications have proven successful uses of the rolled material containing 13-15% manganese and 3-5% nickel. In the cast condition, a similar alloy containing also about 4%

Howard George, Electric Traction, March 1931.

chromium is finding applications in resisting wear combined with temperatures approaching red heat.¹

One of the difficulties experienced with manganese steel is its peening and stretching under heavy pressure. In extreme cases, manganese steel parts will "grow" enough to cut off the heavy bolts with which they are held in place, or to buckle so badly as to interfere with the operation of the machine of which they form a part. This tendency to "grow" has always been taken care of by making such parts enough smaller than the space they are eventually to fill, to permit growth to occur without harmful results.

Many efforts have been made to counteract this tendency, which is due of course to the comparatively low compressive elastic limit of the material, by the addition of other alloys to the steel. Chromium up to some 6%, molybdenum up to about 1%, or combinations of the two, are the alloys usually preferred. Additions of these "hardeners" of sufficient amount to decrease the tendency to peen, decrease the toughness of the steel to a considerable extent. To overcome this loss of toughness, additions of nickel as above described, or of copper up to some 2%, have been sometimes made. Not enough service tests have been carried out on these special compositions to justify a definite statement as to their value, but the indications are that in some cases the extra cost of the alloy is justified by the improvement in the results secured in service.

Pre-Peening—As manganese steel develops its full resistance to wear only after the surface layers have been deformed by pressure and consequently hardened, in some applications of the metal it is advantageous to perform this deformation artificially. This is especially desirable when it is important that the exact shape of the piece be maintained as nearly as possible, as for instance in street and steam railway special trackwork. In these cases, the part is finished to a little above the desired final dimensions, at places where distortion takes place, and these parts are brought to the final dimension by cold working by means of press, hammer or air hammer. In this manner, the part can be shipped in condition to give the best resistance to wear from the start, without being distorted out of shape while developing this desirable condition.

It has not been found economical to utilize this method to improve the wear resistance of manganese steel in classes of service to which it is not otherwise suited, such as described above, because the depth of metal hardened by artificial cold work bears too small a relation to the total thickness to be worn away in service.

Molybdenum Steels

By A. J. Herzig* and W. P. Sykes†

Pure molybdenum is a soft, ductile metal resembling platinum in color. Its physical constants are given in this Handbook under "Physical Constants of the Elements."

The metal is produced by heating one of its several oxides, or ammonium molybdate, in an electric furnace and reducing in hydrogen to pure molybdenum powder. The compressed powder is sintered by passing a strong electric current through it. The resulting ingot is swaged, rolled, and drawn into sheets, rods and wire. The pure metal is used for the spider of incandescent lamps, for parts of radio tubes, X-ray equipment, electrical heating units, and in the manufacture of non-ferrous alloys.

Historical—Molybdenite was first distinguished from graphite and galena in 1778 by C. W. Scheele. In 1782, P. J. Hjelm separated the metal from molybdenite and called it *molybdenum*. Metallic molybdenum was produced by Berzelius at the beginning of the 19th century. Although the presence of molybdenum in alloys of iron was established as early as 1831 by analysis of several iron-rich meteorites, the first intentional production of iron-molybdenum alloys was accomplished by Moissan about 1880 in his work with the electric arc furnace. From this date references to the application of molybdenum became increasingly numerous and at the opening of the 20th century it was in commercial use in high speed steel although this application was short-lived. Studies of molybdenum steels were made by Guillet (1904) and Swinden (1911). Out of the demands of the World War for new materials much information on molybdenum steels was obtained. Molybdenum steel was definitely adopted as a standard specification by one of the large automobile plants in 1920. Since then the commercial use has grown rapidly.

Supply and Production—Although a small amount of molybdenum is recovered from Wulfenite (PbMoO_4), the most important ore of molybdenum is molybdenite (MoS_2). This is a soft, flaky, lustrous mineral, similar in appearance to graphite. Mineralogically, it is widely distributed throughout the world, but commercial occurrences are relatively rare. The largest known deposits are in the United States.

Molybdenite is extracted from its usual low grade ores by fine grinding and flotation concentration. The concentrate, containing about 50% molybdenum and 35% sulphur, is calcined to remove the sulphur and the resultant crude molybdic oxide (MoO_3) is the base material from which the various compounds and alloys of commerce are produced.

Introduction of Molybdenum into the Steel Bath—Molybdic oxide briquettes, a salt of molybdenum (calcium molybdate or calcium molybdenum silicate) or ferromolybdenum may be employed for making additions of molybdenum to the steel bath. The salt or oxide is lower in cost and satisfactory for introducing all fractional percentages of molybdenum. Molybdenum has a low affinity for oxygen and the elements of the steel bath. Molten iron will reduce molybdenum from the slag in which the molybdate or oxide has been dissolved. All other compounds of the salt are slag forming constituents, and only pure nascent molybdenum enters the steel. When more than 1% molybdenum is required, ferromolybdenum is preferably employed.

Effect of Molybdenum in Steel—In solid solution molybdenum is known to expand the space lattice of iron. In steel molybdenum will be found both in the solid solution phase and in the carbide phase. It tends to inhibit grain growth and definitely imparts sluggishness to any structural change which is induced by thermal treatment. This effect is clearly demonstrated by the higher requirements in quenching and tempering temperatures for the heat treatment of steels containing molybdenum. There is strong evidence that molybdenum markedly raises the lowest temperature of recrystallization of iron.

Molybdenum steels require relatively longer soaking periods for annealing and spheroidize more slowly than carbon steels. The depth hardening characteristics are decidedly more pronounced than would be predicted on the basis of the change in equilibrium transformation temperatures. The critical transformation of steel containing molybdenum is sluggish so that with the cooling rates normally

*Chief Metallurgist, Climax Molybdenum Co. of Detroit.

†General Electric Co., Incandescent Lamp Dept., Cleveland Wire Works, Cleveland.

encountered in practice, deep hardening is readily attained. Molybdenum steels are generally characterized by the following properties: Depth hardening; toughness; structural stability; elevated temperature strength; minimum susceptibility to temper brittleness.

Molybdenum in small amounts does not interfere with forging, rolling, machining, carburizing, or welding operations. In many instances steel containing molybdenum is found to harden acceptably from an unusually wide range of heating temperatures. Chromium-molybdenum steel is well known for its self scale freeing characteristics. It is common knowledge that chromium-molybdenum steels of the 4100 series in the fully heat treated condition can be machined at higher hardnesses than other alloy steels of comparable physical properties. In regard to welding, it is claimed that molybdenum is the one element besides phosphorus which can be added to iron without seriously affecting the ability of iron to be welded.

Chromium-Molybdenum Steels—Steels properly alloyed with chromium and molybdenum are characterized by their resistance to impact, fatigue, abrasion and high temperature stress. These steels when suitably heat treated are deep hardening, offer good machinability and are readily welded by either gas or electric methods. The composition for the S.A.E. steels is given in the S.A.E. specification in the Handbook, and the heat treatments for steels here considered are in Table I.

4820	Carburize 1650-1700 ^b	1525-1575	1350-1400 Oil for Case 1450-1500 Oil for Core	"

^aA long soak is recommended. ^bBox quench.

S.A.E. Steel 4130—This composition is recommended for heat treated automobile parts such as driveshafts, rear axle shafts, steering knuckles and arms, connecting rods. Other established applications include aircraft tubing, intake valve stems, drill collars, sucker rods, bolts and studs.

S.A.E. X4130—This analysis has higher chromium and lower manganese than S.A.E. 4130. The most extensive application is airplane construction; it is also used interchangeably with S.A.E. 4130. The heat treatment is the same as for S.A.E. 4130.

S.A.E. 4140—This steel is intended for practically the same purpose as 4130 except that it is oil quenched and the physical properties are slightly higher.

S.A.E. 4150—This steel is recommended for heat treated parts which are subjected to wear, such as gears and roller bearings; also for highly stressed automobile and machine parts.

Nickel-Chromium-Molybdenum Steels—In heavier section, these steels offer the best combination of ductility and strength and the highest fatigue-tensile ratio of any molybdenum S.A.E. steels. Being air hardening, the steels must be prepared for machining by a suitable annealing treatment. Because of their deep hardening characteristics and resistance to softening at elevated temperatures, these steels, with suitable carbon content, are recommended for hot work dies.

S.A.E. Steel 4320—This steel is similar in analysis to S.A.E. 4620 except for the chromium content. Its field of usefulness lies in those carburized parts which require a somewhat harder and stronger core than is normally developed with S.A.E. 4620.

S.A.E. Steels 4340 and X4340—These steels are recommended for oil hardening gears, axle shafts, crankshafts, and heavy duty shafting of large sections. When quenching large section, the best practice is to remove the work from the quenching medium before it becomes cold.

Chromium-nickel-molybdenum steels outside the S.A.E. classifications are often used for parts such as gears, shafts and axles; in the higher carbon range, these steels are recommended for special gears, drop forge die blocks, airplane propeller shafts and heavy forgings.

Nickel-Molybdenum Steels—This alloy combination is characterized by excellent toughness at relatively high hardness. The hardening range is wide and quenching from the carburizing temperature without objectionable distortion or impairment of physical properties may be successfully employed.

S.A.E. 4615 and S.A.E. 4620—These steels are used in carburized gears, cams, and shafts where high fatigue resistance and good toughness are required. They are good carburizing steels from the standpoint of minimum distortion. For best results, after quenching, the carburized article should be held for a prolonged period of time at a low temperature (300-400°F.).

S.A.E. Steel 4640—With its higher carbon content this steel is used for gears, shafts, and parts where high fatigue resistance is required. Like the lower carbon steel, it affords minimum distortion problems.

S.A.E. 4815 and S.A.E. 4820—These steels are used for carburized gears and parts where high core hardness is required.

Carbon-Molybdenum Steels—Cases where the necessity for welding or some other condition which precludes the presence of chromium, form the principal field for the straight molybdenum steels. Among the advantages of this composition are resistance to grain growth and minimum susceptibility to temper brittleness. These steels are adapted to welding and possess excellent creep resistant properties. Representative applications include automobile parts, structural plates, welded pipes, crankshafts, boiler, and still tubes.

Manganese-Molybdenum Steels—Steels containing 1.5-2.5% manganese are generally susceptible to extreme temper brittleness, but the addition of molybdenum strengthens the steels statically and dynamically, minimizes temper brittleness, stabilizes the properties at elevated temperatures, refines the structure, and widens the critical range. Railway rails and locomotive tires, dredge buckets and rock crusher parts and high tensile studs are typical applications.

Silicon-Molybdenum Steels—Molybdenum additions to silicon steel serve to increase toughness, reduce the tendency toward temper brittleness and resist grain growth at elevated temperatures. Chisels, shear knives, hammers and similar shock resisting tools are produced from silicon-molybdenum steels.

Molybdenum High Speed Steel—While the use of relatively small percentages of molybdenum in tool and die steels has been common for a number of years, it is only recently that tool steel in which molybdenum is the chief alloying element has gained much prominence. A steel containing 8.00-9.00% molybdenum with or without 1.50-2.00% tungsten is now being produced commercially. The advantages are: Lower cost, lower density, and lower required hardening temperatures. Susceptibility to surface decarburization when treated in oxidizing atmospheres has retarded its universal acceptance. This surface decarburization is satisfactorily overcome by the use of salt baths, borax coatings, or controlled furnace atmospheres.

Molybdenum Die Steels—Die steels properly alloyed with molybdenum are characterized by deep hardening, resistance to abrasion, heat checking and washing. Hot work tools and dies, forging rolls, punches, upsetting and extruding dies are among the recommended applications.

Corrosion Resistant Alloys—Copper-molybdenum iron is used to resist atmospheric and mild acid attack. In many instances, molybdenum additions to standard 18-8 steels increase the strength of the composition at elevated temperatures and improve resistance to corrosion.

Molybdenum Steels for Elevated Temperature—Molybdenum steels retain their hardness and strength at elevated temperatures. Carbon-molybdenum steels are used in oil refineries for convection tubes and cracking furnace tubes and as steam piping for boiler plants. Repeated tests show resistance of carbon-molybdenum steel to creep to be about twice that of carbon steel at 900°F.

Molybdenum in Steel Castings—The properties imparted to forged and rolled steel by molybdenum are similarly exhibited in steel castings. The following types

are common: Carbon-molybdenum, chromium-molybdenum, manganese-molybdenum, nickel-molybdenum, chromium-nickel-molybdenum.

Carbon-molybdenum cast steel is used for castings required to show good strength at elevated temperatures. Chromium-molybdenum cast steel provides improved depth hardening characteristics to the castings, high temperature strength and abrasion resistance. Special types of chromium-molybdenum cast steel are also used for resistance to oxidation and corrosion. Manganese-molybdenum compositions are used where general improvement of tensile and impact characteristics are required. Chromium-nickel-molybdenum cast steel finds its application in parts where maximum depth hardening characteristics are essential and where severe abrasive service must be withstood.

Mill Rolls—One of the important uses of molybdenum in steel castings is in mill rolls where it is usually employed in conjunction with chromium, nickel, or both. These rolls are characterized by great strength, toughness, density and wearing qualities. The carbon content varies widely from 0.40-2.00% according to the service to be encountered or according to which of the above physical characteristics is of first importance. Heat treatments vary likewise from slow furnace cooling to air quenching followed by tempering. With the heavy masses involved, bath quenching is impractical. Molybdenum is used to advantage in cast steel and cast iron rolls, both chilled and sand cast.

Nickel As An Alloying Element in Steel

Thomas H. Wickenden*

Historical—The occurrence of nickel in meteorites and the working of this material into swords and tools undoubtedly accounts for the first use of nickel steel. Nickel, however, as an element was not recognized until isolated by Cronstedt in 1751. The first published report of its being alloyed with iron was by Stoddard and Faraday¹ in 1820. The next important development was the production started in 1885 by Marabeau of a wide series of iron-nickel alloys and nickel steels. These were studied and tested by James Riley of Scotland and the results were published in his now famous paper of 1889 on the "Alloys of Nickel and Steel." He was the first to demonstrate the general properties of nickel steels and pointed out their commercial value. During this period nickel had gradually become more available and cheaper because about this time nickel was produced in commercial quantities from both the New Caledonian and Canadian ores.

Riley's paper marked the beginning of active engineering and metallurgical interest in these steels. In 1891 the U. S. Navy conducted a competitive test between plain carbon and nickel steel armorplate. The nickel steel proved decisively superior and stimulated a world wide interest in this material for ordnance. In 1899

Hadfield² published an exhaustive paper on the "Alloys of Iron and Nickel." Since then it has been the subject of active interest and investigation by many scientists, and today finds an exceedingly wide field of industrial applications.

Alloying Nickel in Steel—Nickel is a white, malleable, magnetic metal, harder and stronger than iron, and has a melting point of approximately 2645° F. Nickel is supplied in the form of electrolytic cathode of

Fig. 1—Constitution diagram of nickel steel and iron.

high purity (99.90% Ni + Co) sheared to convenient sizes. It is also available in the form of shot and ingot of remelted cathode. As nickel is not oxidized in the bath, in fact nickel is chemically negative to the iron, it may be added at any time practically without loss. Part of the nickel is generally secured by charging nickel steel scrap; the balance may be added with the charge or at sufficient time before tapping to ensure proper diffusion. As nickel has no deoxidizing properties, it does not prevent blowholes, hence the steel to which it is added should be well made. Nickel does check segregation and tends to produce a fine grain primary crystal but is primarily added to steel for its beneficial effect on the mechanical properties.

The Effects of Nickel in Steel—Iron and nickel are soluble in all proportions in the molten state and remain as a solid solution on solidification. At normal temperatures nickel is in solid solution in the iron phase, either ferrite or austenite, depending on the composition. The equilibrium diagram of iron and nickel is given in another section of this Handbook. An examination of this shows some of the fundamental effects of adding nickel to iron. The addition of nickel reduces the temperature of the A_c3 transformation and introduces a considerable spread between the temperature of beginning and the end point. The A_r point is reduced to a still greater extent, in fact with 33-34% of nickel it is not reached at liquid air temperatures.

The constitution diagram for nickel, iron and carbon, after commercial slow cooling, is given in Fig. 1. The graphitizing effect of nickel is shown by the graphite line. The change in structure of these nickel-iron-carbon mixtures as the nickel or carbon is increased is not sharply defined but changes gradually over a considerable variation in composition. This is true when the pearlitic area—generally

¹The Quarterly Journal of Science, Literature and the Arts, 1820, v. IX, p. 324.

²R. A. Hadfield, Alloys of Iron and Nickel, Proc., Inst. Civil Engrs. (London), 1899, v. 138, p. 1.

as a fine grained sorbite—enters the martensitic area by showing some martensitic needles.

Because traces of austenite soon make their appearance, the range where martensite alone is found is rather narrow. The martensitic structure in the lower carbon range is often difficult to identify as it will show martensitic like needles but does not possess the hard properties characterizing this constituent. The mixed structure of martensite and austenite extends over a broad area, the last traces of martensite persisting up to a fairly high nickel content under conditions of slow cooling.

Fig. 2—Comparative physical properties of nickel steels with 0.25% carbon. Not heat treated (Bullens).

The general effect of increasing quantities of nickel on the mechanical properties of a cast nickel steel with 0.25% carbon is illustrated in Fig. 2. The strength is gradually increased, reaching a maximum of 180,000 psi., with 12% of nickel. Data on carbonless nickel-iron alloys, annealed, by Burgess and Ashton show the same maximum strength, but at 18% of nickel. The strengthening effect of nickel on ferrite should be noted as it offers a means of strengthening low carbon steels without heat treatment. Carbon has the effect of shifting the diagram to the left and accentuating the martensitic stage. It should be noted from

the diagram that the abrupt changes in mechanical properties correspond to the changes in the micro-constituents of the steel.

Classification of Nickel Steel—Characteristics of the 3 groups of steels pearlitic, martensitic, and austenitic are discussed in detail.

The Pearlitic Steels—The pearlitic group, steel containing from 0.5-6.0% nickel, is most widely used commercially. The principal effects of nickel on this group of steels are as follows:

Fig. 3—Effect of Nickel on the AC Critical Range.

1. Nickel depresses the critical point and lowers the eutectoid ratio. The effect of nickel in lowering the Ac critical range is well illustrated by Scott¹ in Fig. 3. He further states that the Ac₁ is lowered 18.9°F., the Ar₁ 38.7°F., and the eutectoid ratio is decreased approximately 0.042% carbon for each per cent of nickel added. Thus, with a normal eutectoid ratio of 0.90% carbon in plain carbon steel this is reduced to approximately 0.75% for 3.5% nickel and 0.70% for 5.0% nickel steel. The lower critical range allows the use of lower quenching temperature when heat treating nickel steels, and consequently results in less scaling, warping, and cracking of the part. This also permits a saving of fuel and less wear on the heat treating equipment.

2. Nickel increases the strength, yield point, and hardness without a corresponding loss of ductility in both the annealed and heat treated steels. The following table gives data on an annealed 0.30% carbon steel with different nickel contents.

Carbon	Nickel	Tensile Strength, psi.	Yield Point, psi.	Elongation in 2 in., %	Reduction of Area, %	Brinell Hardness No.
0.30	0	70,000	40,000	26.0	50.0	145
0.30	3.50	90,000	60,000	27.0	55.0	175
0.30	5.00	95,000	65,000	28.0	56.0	185

These characteristics of nickel are utilized in rolled structural shapes, boiler plates, and large forgings or castings which, due to size or shape, are impractical to heat

¹Bur. Standards Bull. No. 376, p. 212. Critical Ranges of some Commercial Nickel Steels.

treat beyond normalizing and annealing. Nickel, often in combination with copper, is used in many of the recently developed high tensile, medium corrosion resistant steels which are generally used in the as-rolled condition. In some of the nickel-copper steels the tensile strength can be further increased by precipitation hardening treatment.

Abbott,⁴ after a great many tests, observed the average effect of nickel up to 8%, for fully annealed steel, to be as follows:

1.0% of nickel increased the elastic limit.....	4,000 psi.
1.0% of nickel increased the tensile strength.....	4,200 psi.
1.0% of nickel increased the reduction of area.....	0.5%
1.0% of nickel decreased the elongation.....	1.0%

If steels of the same strength and similar treatments are compared, the advantages of nickel in increasing the yield point, impact, fatigue limit, and fatigue ratio are very evident. The following results taken at mid point in 6 in. forgings, normalized and tempered illustrate these points:

C	Mn	Ni	Yield Point, psi.	Tensile Strength, psi.	Izod Impact, ft.-lb.	Fatigue Limit, psi.	Fatigue Ratio %	Brinell Hardness
0.46	0.64	51,300	86,200	16	40,000	47	167
0.24	0.94	2.70	57,800	87,800	86	54,000	61	183

In heat treated steels the benefit of nickel is still more evident as shown by the following results from a 0.40% carbon steel and a 3½% nickel steel.

Steel	Heat Treatment	Tensile Strength, psi.	Yield Point, psi.	Elong. in 2 in., %	Red. Area, %	Izod Impact, ft.-lb.
0 Nickel	1500°F.—Water; 1300°F.	90,000	53,000	25	62	59
3.5% Nickel	1425°F.—Oil; 1250°F.	109,000	85,000	25	62	76
0 Nickel	1500°F.—Water; 980°F.	125,000	82,000	18	51	36
3.5% Nickel	1425°F.—Oil; 1090°F.	126,000	104,000	23	60	59
0 Nickel	1500°F.—Water; 600°F.	150,000	112,000	9	34	13
3.5% Nickel	1425°F.—Oil; 910°F.	150,000	137,000	18	56	36

3. Nickel slows down the critical rate of hardening. This property affects its use in several ways. Oil can be used as a quenching medium which reduces the danger of warping or cracking on intricate shapes. The depth hardening properties of nickel steels can be greatly augmented by the addition of molybdenum or chromium; with these additions parts of large size can be hardened to considerable depth. Slow cooling tends to produce a fine grain pearlite tending toward sorbite.

Fig. 4.—Variation in the true coefficient of linear expansion of nickel steels at various temperatures (Chevenard).

uniformity of carbon penetration. They are amenable to a single quenching treatment; they develop greater core strength; and the case is tougher as shown by a smaller tendency of the nickel steels to show grinding cracks. The case will develop file hardness on oil quenching.

⁴R. R. Abbott, In his: *Rôle of Nickel*. Proc., A.S.T.M., 1917, v. 17, pt. 2, p. 11.

5. Nickel increases the resistance to fatigue endurance ratio. McAdam⁵ states the addition of nickel to annealed carbon steel apparently strengthens the ferrite with the result that the endurance ratio is raised. The full effect of nickel on the endurance ratio, however, is obtained only by quenching and tempering.

6. Nickel increases the resistance of steel to corrosion. This is easily demonstrated by the resistance to etching shown by 5.0% nickel steels. The use of nickel in the high tensile, medium corrosion resistant steels has been mentioned above.

7. Nickel improves the impact properties of steel as shown in the table above. This shows that at equal tensile strengths the nickel steel is tougher and has greater resistance to shock, especially as the tensile strength is increased. Nickel toughens steel at low temperatures and its favorable influence is exerted alike on cast and wrought steels. Room temperature tensile and low temperature impact properties of normalized and tempered, rolled 2% nickel steel and a double normalized and tempered, low carbon, cast 3½% nickel steel are shown in the following:

% C	% Mn	% Ni	Yield Point, psi.	Tensile, psi.	Elong., %	Red. Area, %	Charpy Impact, ft.-lb. Keyhole Notch			
							70°F.	-75°F.	-150°F.	-200°F.
0.08	0.48	1.99	47,000	61,500	40.0	70.0	63	62	39	26
0.13	0.65	3.50	53,500	80,000	32.0	60.0	38	26	20	18

Both steels were treated with 0.08% aluminum. The tempering temperature was 1200°F.

8. Nickel is extensively used in welding grade of steels. As nickel strengthens ferrite without the presence of carbon, it does not increase the weld hardness as drastically as some of the carbide forming elements. It is widely used in conjunction with other alloys in the high elastic steels of welding quality.

The nickel-chromium steels are produced with a wide variety of compositions. The analyses, properties, and further data on the applications and heat treatment of these alloys are given in other articles of this Handbook and the S.A.E. Handbook.

Nickel-molybdenum makes an excellent carburizing steel and nickel-chromium-molybdenum an excellent steel for heavy sections requiring high strength and good impact properties.

Nickel-silicon and nickel-silicon-molybdenum steels were developed during the late war period for light armor plate. They show unusual combinations of properties at high strengths.

Martensitic Steels—This group with 10-22% of nickel is not much used. The steels are hard, almost impossible to machine; certain combinations are brittle, and give very little response to heat treatment.

Many corrosion resistant steels will be found with nickel within this range but it is usually in combination with other elements which tend to make the steel austenitic.

Austenitic Steels—The austenitic range of nickel steels presents a most fascinating study as their properties are so varied that they constantly unfold new and interesting engineering and scientific applications.

The straight iron-nickel group has a variety of uses as follows:

25-30% Nickel—Alloys with this nickel range are used for corrosion resistance and for low temperature electrical resistance wire.

20-30% Nickel—Steels with this nickel range are nonmagnetic after cooling at normal rates from forging or rolling temperatures to atmospheric temperature. Their magnetic condition can be restored by cooling to liquid air temperature.

30-40% Nickel—This nickel range presents an interesting anomaly in coefficient of expansion. As the nickel content is increased above 30%, the coefficient of linear expansion is rapidly lowered until it reaches a minimum of nearly zero coefficient between 35 and 36% of nickel. This phenomenon was discovered by Guillaume, and to carefully prepared and heat treated alloys of this composition he gave the name of "Invar." In its finer state it is used for the production of fine instruments, standard bars, measuring tapes, clock pendulums, balance wheels of watches, and as one of the bimetals used for thermo controls. In a more commercial grade with wider range of nickel this alloy is finding use as struts in aluminum pistons to control the overall expansion to that of cast iron. At elevated temperatures the point of minimum expansion is lower with higher nickel ratios as is shown in Fig. 4.

Elinvar—Elinvar is an alloy having a nonvariant elastic modulus with tem-

⁵D. J. McAdam, Jr., On Endurance Properties of Steel, A.S.T.M. Proc., 1923, v. 23, pt. 2, p. 99.

perature change. It was developed by Guillaume and the original composition contained approximately 36% of nickel and 12% chromium. This composition has been modified so that most of the Elinvars used for hair springs have a chromium range of 4-5%.

Platinite—Platinite is a nickel steel with about 46% nickel which has the same coefficient as platinum.

50% Nickel—An alloy of 50% nickel and iron is used for its magnetic properties, having a high permeability at low field strengths. It is finding application in the radio field.

78.5% Nickel—This is another magnetic nickel-iron alloy with high permeability at low field strengths; also the magnetic hysteresis loss is very low. It is finding use in telephone equipment and as loading tape in submarine cables. It is known as Permalloy.

Nickel in Cast Steel—Nickel is extensively used as an alloy addition to cast steels. The amount used varies from 0.5-5% and is often used in conjunction with other alloying elements. Analysis, heat treatment, and mechanical properties of cast nickel steels that have been widely used are given in Table I.

Corrosion and Heat Resisting Alloys—Nickel is one of the important constituents in this group of alloys and is used in a wide range of compositions in combination with many other elements. For further information on compositions, see the sections of this Handbook dealing with stainless steels and trade names of corrosion and heat resisting alloys.

Properties of Iron-Nickel Alloys

By J. W. Sands*

Iron and nickel are soluble in all proportions in the molten state and form solid solutions on solidification. The alloys at room temperature may be either

Fig. 1—Comparative physical properties of nickel steels with 0.25% carbon. Not heat treated (Bullens).

Fig. 2—Variation of electrical resistance with nickel content in iron-nickel alloys. Multiply by 6 to convert to ohms per mil. ft.

Fig. 3—Variation of thermal conductivity (Cgs. units) with nickel content in iron-nickel alloys. Multiply by 2900 to convert to English units. (Ingersoll.)

36% nickel, but increases on either side of this composition, making it possible in the

ferritic or austenitic in nature depending upon the nickel content and in some cases on the thermal history of the sample. Additions of carbon also affect the phase relationships. Nickel progressively lowers the transformation temperature of iron, imparts a considerable hysteresis in the temperature of its occurrence on heating and cooling, and introduces a considerable spread between the temperature of beginning and end points. The lowering of the Ar range is so pronounced that at a nickel content of about 34% the transformation cannot be reached even at the temperature of liquid hydrogen (20°C. above absolute zero). Hence all the alloys containing nickel in excess of this amount are austenitic (face-centered cubic) under all conditions. See page 386 on the constitution of iron-nickel alloys.

Alloys of lower nickel content may be either ferritic or austenitic or a mixture of both, depending on the thermal history of the sample. Under ordinary conditions of commercial slow cooling, the alloys with between 10-25% nickel possess a martensite-like structure which is relatively hard and non-ductile. Little commercial use is made of alloys in this range.

Under the same conditions of slow cooling, carbon-free alloys containing less than 10% nickel are simple, single phase solid solutions of nickel in alpha iron. In the presence of carbon these alloys become amenable to the ordinary methods of heat treating steel and, in general, assume the usual microstructures associated with pearlitic steels, although some austenite is likely to be retained in the case of the higher nickel contents. Nickel contents up to 6% are used commercially in automotive and engineering steels to provide advantages discussed elsewhere in this book. For similar reasons nickel in these proportions is also widely used in engineering cast irons.

The iron-nickel system exhibits several anomalies with respect to thermal expansion, magnetic and thermoelastic characteristics which are used to advantage in a number of special purpose alloys. Thermal expansion over an appreciable temperature range becomes practically negligible in the vicinity of

*Development and Research Division, International Nickel Co., Inc., New York.

30-60% nickel range to select alloys of appropriate expansivity to fit particular applications. The widest usage of these materials is for the low expansion side of thermostatic bimetal. The high expansion side also is frequently an iron-nickel base alloy with an addition of chromium. A favored composition is 22% nickel and 3% chromium. See page 465 for additional information.

Fig. 5—Density of iron-nickel alloys.

Fig. 6—Variation of modulus of elasticity with nickel content.

ordinary atmospheric temperatures and therefore shows a variable magnetic permeability in this temperature range. This makes the alloy valuable for temperature compensating shunts in watt meters and other electrical devices. Alloys lower in nickel content are above their magnetic change point at room temperature and therefore nonmagnetic, provided they are fully austenitic. If more than 20% nickel is present, air cooling is sufficiently rapid to suppress the $\gamma - \alpha$ phase change, so that these alloys are useful for applications requiring nonmagnetic metals of good strength, high toughness and favorable corrosion resistance. For reasons of economy, however, it is the usual practice to reduce the nickel content and restore austenite stability through additions of manganese and chromium. The same method is followed in the production of nonmagnetic cast irons, some of which contain copper.

In the range of stable austenitic iron-nickel alloys containing from 35-90% nickel there have been developed a number of alloys possessing extremely useful magnetic characteristics. One of the important properties of these materials is high permeability under the influence of weak magnetic fields making them valuable as loading materials in electrical communication circuits. Continuous loading of transoceanic cables with 78.5% nickel ("Permalloy") strip resulted in speeding up transmission fivefold.

These alloys as a class show high permeability and low hysteresis loss. By varying the percentage of nickel and judicious addition of other elements, such as cobalt, copper, molybdenum, and chromium, various characteristics may be emphasized and different combinations of magnetic properties secured. The latter two

Most metals possess a negative thermal coefficient of the elastic modulus, that is, they lose stiffness with increasing temperature. Iron-nickel alloys with nickel between about 27-44% exhibit a positive coefficient, reaching a rather high maximum at about 36%, which is also the point of minimum thermal expansion. This property is of value for certain temperature compensation applications. Composite springs of steel and 36% nickel-iron can be made to maintain a constant stiffness in the face of temperature fluctuations due to the opposing effects of temperature on the moduli of the two materials.

Replacement of some of the iron in the 36% nickel-iron alloy with chromium progressively lowers the positive thermoelastic coefficient until at some 8-12% chromium it is practically zero. Constant modulus alloys of this type, with additions of certain other elements to improve the elastic limit, are useful for hair springs in timekeeping devices, scale springs, tuning forks, and bourdon tubes.

The austenitic iron-nickel alloys are magnetic at all temperatures below the magnetic transformation point, which temperature varies with composition. In the ferritic condition they will always be magnetic, but in the austenitic condition this will depend on their position with respect to the magnetic transformation curve.

The austenitic 30% nickel alloy is in the magnetic transformation range at

elements are particularly useful in increasing the electrical resistivity, thus reducing eddy current losses.

Thus in the iron-nickel series there exist alloys varying all the way from the completely nonmagnetic to those offering maximum magnetic softness. It was discovered by Mishima in Japan that additions of aluminum to appropriate nickel-iron alloys would produce materials of high magnetic hardness. Such alloys now find extended use for permanent magnets since they provide more magnetic energy per unit of volume than any other permanent magnet material commercially available. They are made in several grades, some containing, in addition to the nickel and aluminum, various combinations of cobalt, titanium, and copper. The nickel content is usually 20-25% and the aluminum 10-15%.

Variations with nickel content of some of the important physical properties of the iron-nickel series are shown in Tables I and II and Fig. 1-7.

Silicon As An Alloying Element in Steel

By W. E. Ruder*

Physical Constants—The physical constants for the element silicon are given elsewhere in this Handbook.

General—Next to oxygen the element silicon is the chief constituent in the solid crust of the earth, where it occurs as the oxide, SiO_2 , in various forms, such as sand, quartz, flint, opal, or in silicates. It may be obtained as an amorphous powder or in crystalline form by reduction with aluminum, magnesium, or carbon. Pure crystalline silicon in mass has an opaque, metallic appearance. The oxide is acid in its reaction and combines readily at elevated temperatures with most metallic oxides to form silicates.

Source of Silicon in Steel—The silicon content of basic open hearth or Bessemer steel is usually under 0.01%, unless it is added during the finishing period of the heat. Under certain conditions acid open hearth steel may, without the addition of silicon, contain 0.25-0.35% silicon.

The source of silicon in basic steel is from the silicon in the pig iron and scrap used, and in acid steel, from the pig iron, scrap, and acid lining.

The silicon content of pig iron is derived from the reduction of the silica in the ore by coke. The amount of silicon in the iron depends primarily on the temperature and the type of slag used. The approximate silicon content of pig iron is as follows:

Pig Irons	% Silicon
Basic	about 1.00
Bessemer	1.00-2.00
Foundry	1.25-2.75
Scotch	3.00
Silvery	3.00-5.00
Softener	8.00

Ferrosilicons are usually referred to by the silicon content as 10 or 15% silicon pig, 50, 75 or 90% ferrosilicon. Ferrosilicon is usually, and in the higher percentages always, made in the electric furnace. Silico-spiegel is a blast furnace product containing 6-12% silicon and 17-22% manganese. Silico-manganese is an electric furnace product containing from 18-25% silicon and from 60-70% manganese. Most of the silicon introduced into the metal by the pig iron is oxidized during the process of steel making, but more is added at the end of the process to deoxidize and produce a sound product if killed or semikilled steel is desired. Such addition is usually made to the ladle in the form of 50% ferrosilicon. The silicon reduces the iron oxide present to form silica (SiO_2) or complex silicates most of which, if given time, will combine with the slag. The mechanism of its action in producing sound steel, namely, steel free from blowholes, is not definitely known at present. Silicon is a more efficient deoxidizer than manganese, but does not give the beneficial effects that manganese does in the rolling of steel.

The use of an alloy of 4:1 or 7:1 manganese to silicon ratio is finding increasing favor as a deoxidizer for open hearth steels.

Toxic gases, principally phosphine and arsine, are given off by impure ferrosilicon in contact with moist air. Calcium carbide will cause disintegration of ferrosilicon in the presence of moisture.

Critical Points—Silicon has a marked effect upon the critical points. With increasing silicon in low carbon alloys the A_1 point decreases in intensity and disappears entirely at about 2¼% silicon. The magnetic transformation (A_2) is depressed about 9°C. (17°F.) per 1% silicon up to 4%. From 4-15% the rate increases to 22°C. (39.5°F.) for each per cent of silicon added. The closed gamma region extends to 2¼% silicon in very low carbon alloys and to about 5% with 0.2% carbon present.

*General Electric Co., Schenectady.

In high silicon transformer sheets the magnetic transformation (A_s) occurs at approximately 730°C. (1346°F.).

Effect of Silicon on Physical and Mechanical Properties—The *specific volume* increases from 0.128-0.138 at 14% silicon, from 0.138-0.165 at 33% silicon, from 0.165-0.225 at 57%, and from 0.225-0.440 for 100% silicon. The *density* falls off from 7.89-7.5 with added silicon up to 5%. The *specific heat* in the room temperature range is increased from that of iron, 0.102-0.1298 for 10% silicon, 0.1448 for 50% silicon, and 0.1652 for 95% silicon. The *thermal expansion* of iron-silicon alloys decreases with increasing silicon content. Up to 4.5% silicon increases the tensile strength and yield point, but a further increase in silicon causes a rapid decrease. The elongation and reduction of area show little change up to 2.5% silicon, beyond which, however, increased silicon causes these properties to fall off rapidly.

Silicon in Cast Iron—Silicon and carbon are the principal elements affecting the properties of cast iron. Increasing the amount of silicon added to iron results in a progressive reduction of the melting point from 1530°C. (2786°F.) for pure iron to 1205°C. (2201°F.) for 20% silicon. For any given carbon content an increase of silicon from 1-3.5% changes the structure of cast iron from hard brittle white iron successively to mottled, pearlitic, gray, and "open" structure. These structures are further modified by the degree of superheat and by mold temperature used, but the really important influence of silicon on cast iron is its graphitizing effect on the carbides.

Chemical ware castings obtain their resistant properties from the compound Fe_3Si , which contains 14.5% silicon. No increase in resistance to corrosion is observed under 10% silicon. Such castings usually contain 0.5-1.0% carbon, 0.3-0.8% manganese, and sometimes a little nickel.

Silicon in Tool Steel—In carbon tool steels where silicon may be present in percentages from 0.10-0.60%, increase in silicon content is accompanied by an increase in depth of hardness penetration after quenching. In lower carbon alloy tool steels, silicon in percentages from 0.75 up to 2.50% is used in connection with other elements such as manganese, molybdenum, vanadium or chromium to produce an increase in ductility without loss in tensile strength or hardness.

Silicon in Stainless Steels—One-half to 4% of silicon in stainless steels, of the 18-8 type, appreciably increases their resistance to certain types of corrosion and to high temperature oxidation. It retards hardening and tends to increase brittleness in these alloys. A 12-14% chromium stainless iron containing 2% or more of silicon cannot be hardened, except by cold work. Gas engine valve steels are much improved by the addition of silicon. These steels have about 6-9% chromium, 1-4% silicon, and 0.5% carbon. The A_1 point of these steels is rapidly raised by the addition of silicon to 1000°C. (1832°F.) for 3.5% silicon.

Silicon in Structural Steels—Silicon in structural steels is best known as an alloy with manganese for spring steels. A steel of approximately 0.5% carbon, 0.7% manganese, and 2% silicon, oil quenched from 900°C. (1652°F.) and tempered at 455°C. (851°F.) gives excellent strength and toughness and is widely used for leaf and coil springs. Chromium-manganese-silicon, silicon-chromium, and silicon-vanadium steels are also used. A low silicon steel of approximately 0.20-0.40% carbon, 0.60-0.90% manganese and 0.20-0.35% silicon has been a standard for high stressed structural members in this country for a number of years. Recently the Germans have started to manufacture similar steels, using 0.80-1.00% silicon and 0.50% manganese. "F" or Freund Steel contains about 0.12 carbon, 0.40-0.70 manganese, and 0.75-1.50% silicon.

Magnetic Alloys—Silicon increases the electrical resistivity of iron 11.4 microhms per cm. cube for each per cent of silicon added. By decreasing the solubility of ferrite for carbon and by promoting grain growth, silicon decreases the hysteresis loss. These factors are very important in magnetic circuits of electrical machinery, so silicon alloy sheets are used in almost all magnetic circuits where alternating current is used. For the best results all other elements, particularly carbon, oxygen, and sulphur, should be as low as possible. Low silicon (0.75-3.0%) alloys are also excellent for relay cores.

Grades of Electrical Sheets—Electrical sheets, as these magnetic alloys are usually referred to in the industry, are divided into five general classes as referred to below, with standard guarantee losses for three gages most commonly used.

These loss figures are for standard Epstein samples cut half with and half across the rolling direction from annealed sheets.

Electrical sheets are usually made in basic open hearth or electric furnaces. Sheets are usually hot rolled and to be acceptable should be flat, free from loose

Grade	Uses	% Silicon	Loss 60-Cycle 10,000 B Watts per lb.		
			0.014 in. (29 Gage)	0.0187 in. (26 Gage)	0.025 in. (24 Gage)
"Armature"	Generators; small motors	0.5	1.30	1.55	1.98
"Electrical"	Generators; small motors	1.0	1.17	1.35	1.70
"Motor"	Induction motors	2.5-3	1.01	1.14	1.30
"Transformer I"	Generators and low freq. trans.	3.25-4	0.82	0.94	1.10
"Transformer II"	60 cycle transformers	4-5	0.60-0.52	0.74	0.85

or heavy scale, and thoroughly annealed. Silicon increases the brittleness of sheets and for that reason 4% is about the practical limit for structures subject to strain or vibration. For transformers 4.75-5% silicon is commonly used, and for the minimum watt losses and maximum permeability 6.25% silicon sheets are being made. This is the amount of silicon corresponding to zero magnetostriction.

A typical composition of high grade transformer sheet is:

Silicon	4.50-5.00%
Manganese under	0.10%
Phosphorus under	0.02%
Sulphur under	0.02%
Carbon under	0.05%

Carbon, oxygen, and sulphur are considered to be the most injurious of the impurities.

Magnetic alloys in the form of cold rolled strip are finding increased use in the electrical industry. These contain from 0.5-3.5% silicon and are graded the same as sheets. In the thinner strip, that is, under .018 in. and having a high degree of cold reduction, wide differences in quality with rolling direction are noted.

Heat Treatment—The heat treatment of magnetic alloys is governed somewhat by the rolling procedure in that the finished grain size is important. The temperature should be above 800°C. (1475°F.) and should not exceed 900°C. (1650°F.) if any oxidizing conditions are present. The heating and cooling may be as rapid as possible consistent with the achievement of flat sheets, a consideration of first importance. In the lower silicon grades the cooling rate should be slow enough to allow for the precipitation of the carbides as graphite. In the range of 700-500°C. the rate should not be less than about 12°C. per hr. to prevent abnormal brittleness. Electric furnaces are being extensively used for annealing due to the greater ease of control of temperature and atmosphere which they afford.

Tungsten as an Alloying Element in Steel

By J. L. Gregg*

The Metal Tungsten—Tungsten is a very refractory and heavy metal. Its melting point is 6150°F. and its density approximately $2\frac{1}{2}$ times that of iron. The metal may be obtained in a state of high purity by hydrogen reduction of its oxide, and in such a state it is sufficiently ductile to swage and be drawn into fine wire. Although metallic tungsten is used in electric lamps, X-ray tubes, and in electric contacts it has been estimated that from 95-98% of the tungsten consumed is used in the manufacture of steels.

Tungsten Ores—Metallic tungsten is never found free in nature. The ores from which it is commercially obtained are wolframite and scheelite. Wolframite has the formula $\text{FeMn}(\text{WO}_4)$, varies in composition from FeWO_4 to MnWO_4 , and contains from 60-70% WO_3 . Wolframite containing less than 20% manganese tungstate is called ferbrite and that containing less than 20% iron tungstate is called hubnerite. Scheelite is calcium tungstate (CaWO_4), containing 80.6% WO_3 and 19.4% CaO .

While tungsten minerals are widely distributed over the world, Asia is the largest producer of tungsten ore. In 1936 approximately 70% of the world's output of tungsten was furnished by Asia, most of this ore coming from China and Burma. In some districts of China the ore instead of being mined is gathered from the foot of hills and from streams, where it has been washed by heavy rainfall.

Methods of Adding Tungsten to Steel—Most tungsten steel is made with ferrotungsten, but tungsten can be added to steel by reduction from ore added to the steel making furnace. Ferrotungsten is made by the reduction of tungsten ore, which also contains iron, with either carbon or silicon in the electric furnace. The ordinary ferrotungsten of commerce contains approximately 80% tungsten and less than 0.75% carbon. Practically all of the ferrotungsten used in this country is within the following composition limits:

Tungsten 75-80; carbon 0.40-0.60; phosphorus 0.05; sulphur 0.06; silicon 0.75; manganese 0.80; copper 0.10; arsenic 0.10; antimony 0.05; tin 0.06.

Constitution of Tungsten Steels—Tungsten, like chromium, is a carbide forming element and belongs to that group of elements that tend to suppress the gamma phase of iron. There are two tungsten carbides, WC and W_2C . The former has been detected in steels but not the latter. In the iron-tungsten system there is a compound Fe_3W_2 , which has been observed in low carbon steels, but which probably is rarely formed in commercial tungsten steels, which are mainly steels with a relatively high carbon content. In the ternary system iron-tungsten-carbon there is a compound $\text{Fe}_3\text{W}_2\text{C}$ or $\text{Fe}_3\text{W}_2\text{C}$ and this complex carbide forms in most commercial tungsten steels. There are reasons for believing that this carbide is metastable and that it decomposes to form WC just as cementite in simple iron-carbon alloys decomposes to form graphite. Much of the iron-tungsten-carbon diagram has been worked out, but the apparent diagram is too complicated to permit description in the limited space available here. The findings in regard to the diagram have been reviewed by the author in the book "Alloys of Iron and Tungsten," published in 1934. Also see the article in this Handbook entitled "The Constitution of Iron-Tungsten Alloys."

Tungsten Steels—The preponderant use of tungsten in steels is in tool and die steels. Formerly tungsten magnet steel containing in the neighborhood of 5% tungsten was widely used, but this steel has been superseded by the cheaper chromium steels and the more expensive, but magnetically stronger, cobalt steels and other complex alloys. Some tungsten is used in steels having a high strength at elevated temperatures, usually together with chromium.

Tool and die steels contain as little as 0.5% tungsten, as some oil-hardening, high-carbon steels, and as much as 20% tungsten, as high speed steel. Practically all of these steels contain chromium as well as tungsten. An extensively used steel of the low alloy type is the "fast finishing" steel, used for taking light cuts at high speeds. This type of steel contains from 1.0-1.3% carbon, 1% tungsten, and may contain a fraction of a per cent of chromium and vanadium.

*Bethlehem Steel Co., Bethlehem, Pa.

Table I
Commercial Steels Containing Tungsten and Their Applications

Type Composition, %				Used for
Carbon	Tungsten	Chromium	Vanadium	
0.50-0.65	0.50- 2.00	Chisels.
0.65-0.80	4.50- 7.00	Permanent magnets.
1.00-1.20	1.25- 2.50	Keen edged tools, taps, and chasers.
1.00-1.20	1.00- 2.00	0.50-1.00	Keen edged tools, taps, and chasers.
1.10-1.30	4.50- 6.00	1.00-1.50	For finishing tools, for gun rifling.
0.30-0.45	8.00-11.00	2.50-3.50	0.30-0.60	For hot-working dies and shears.
0.30-0.55	1.50- 2.50	1.25-2.00	0.15-0.40	For hot-working dies, chisels, and punches.
0.50-0.70	1.50- 2.00	0.50-1.00	For valves for gasoline motors.
0.50-0.70	12.00-15.00	3.00-4.00	For valves for gasoline motors.
0.60-0.70	1.00- 3.00	For making gun and Howitzer linings.
0.50-0.80	12.00-20.00	2.50-5.00	0.50-2.25	The very broad analysis of high speed steel, with innumerable uses.
(With or without other elements)				

The high speed steel most widely used in this country contains 18% tungsten, 4% chromium, and 1% vanadium; it is commonly known as the 18-4-1 type. Other types of high speed steels used here contain either more or less tungsten, more vanadium, several per cent of cobalt, or at least part of the tungsten has been replaced by molybdenum. Die steels may contain almost any amount of tungsten up to 20% depending on the service for which they are intended. Compositions of some types of commercial tungsten steels are given in Table I; which was compiled by J. P. Gill of the Vanadium Alloys Steel Co.

Vanadium Steels

By Jerome Strauss* and George L. Norris†

Vanadium—The metallic element vanadium is grayish-white in appearance, nonmagnetic, and has a high electrical resistivity. It is one of the least volatile metals at the melting point. Extremely difficult to reduce to the pure metallic state from its oxides, it is only recently that a purity of 99.7% vanadium has been obtained by Marden and Rich. The metal was malleable and was rolled and drawn into wire.

The physical constants for vanadium are given in the article Physical Constants of the Elements, in this Handbook. No important industrial uses of the pure metal have been developed.

Historical—Vanadium was first discovered in brown lead ore by the Mexican chemist, Del Rio, in 1801. In 1830 the Swedish chemist, Sefstrom, detected it in some remarkably soft, ductile iron produced from an ore at Taberg, Sweden. In 1896 vanadium was first used experimentally in the manufacture of armor plate at the Firminy Steel Works, France. However, it was not until the comprehensive investigation of Arnold in 1900-1901 that vanadium began to receive attention as an alloy for steel. In 1904 Sankey and Smith presented a paper before the British Institute of Mechanical Engineers giving the results of their investigations on chromium-vanadium steels. This paper really marks the beginning of vanadium steel as a commercial product. The discovery within the next year of the large, rich deposit of vanadium ore in Peru immediately made vanadium available in quantities to meet the requirements of the steel industry.

Occurrence and Extraction—Vanadium is one of the most widely distributed of the elements, occurring in small percentages in granites, sedimentary rocks, and clays, and also in many iron, lead and copper ores, bitumens, and petroleum.

The principal sources of vanadium are the minerals patronite, descloizite, cuprodescloizite, mottramite, vanadinite, carnotite, and roscoelite. Patronite is a vanadium sulphide intimately associated with carbonaceous material and occurs in this form, with more or less oxidized modifications, only in the high Andes of Peru. Descloizite, cuprodescloizite and mottramite are vanadates of lead with zinc or copper or both, and are found in commercial quantities in Rhodesia and South West Africa. Vanadinite is a chlorovanadate of lead occurring in the southwestern United States, Transvaal and Spain. Carnotite (a uranyl-potassium vanadate), roscoelite (a vanadium mica) and a vanadium impregnated sandstone often erroneously called roscoelite occur in Colorado and Utah.

Vanadium is reduced from these ores to form ferrovanadium either directly by means of carbon in the electric furnace or from previously prepared vanadium oxide by the silico thermic method in the electric furnace or by the aluminio thermic method without the application of external energy. Vanadium oxide for these reductions and for chemical uses is prepared by roasting ores with sodium compounds to form sodium vanadate followed by precipitation with sulphuric acid from the neutralized vanadate solution.

The compositions of the standard alloys employed in ferrous metallurgy and their methods of use are given in the article Metals and Alloys Used in the Manufacture of Steel in this Handbook.

Production and Price Statistics—In the Table below are recorded the total vanadium content of ores mined throughout the world and the approximate average

Vanadium Production and Price Statistics

Year	World Production of Vanadium in Ores and Concentrates (Metric Tons)	Price of Ferrovanadium in the United States* (Per lb. contained V)
1910	875	\$4.50
1915	1372	2.50
1920	1589	7.00
1925	725	3.30
1930	992 ^a	3.15
1931	661 ^a	3.13
1932	857	2.99
1933	56	2.62
1934	170 ^a	2.80
1935	416 ^a	2.80
1936	975	2.80
1937	1893	2.80

*Excludes ores mined in the United States.

^aApproximate average of all grades throughout year.

*Vice Pres. and †Chief Metallurgical Engineer, Vanadium Corp. of America, New York.

price of the metal in the form of ferrovanadium during the period of major growth of the alloy steel industry. The figures are in most instances approximations due to the difficulty of securing accurate statistics but the trend is shown reasonably well.

Effects of Vanadium in Steel—Vanadium lessens coarse crystallization and grain growth and influences the manner of solution or precipitation of the carbide in or from the solid solution, iron-rich matrix.

The first effect accounts for smaller dendrites in steels as cast, for uniform fine grain size in annealed or normalized, or quenched and tempered steels, without the coarse precipitation of carbide in ferrite known as "abnormality," and for interference with grain coarsening when heating above the temperature range ordinarily employed for heat treatment. The second effect, involving slow solution of the last traces of carbide at heat treatment temperatures accounts for the wide heat treatment range and the benefits it confers, for example, upon articles having both heavy and light sections; it also accounts for the resistance of vanadium steels to tempering and for the occurrence of carbide precipitation at high tempering temperatures. The fine grain size of vanadium steels is conducive to shallow hardening. In some steels this is required, and where uniformity in the hardening depth is important vanadium in small amounts is used to secure this end. When the toughness characteristic of fine grain size is desired along with deeper hardening, other alloying elements are used with vanadium.

Vanadium steels are readily cast, forged or rolled. In machining, these steels are no more severe upon cutting tools than are other alloy steels of equal strength or hardness. Since the grain of vanadium steels coarsens in a narrow range of temperature, only somewhat above the range employed for normalizing or hardening, machining to a smooth surface is readily attainable by such high temperature normalizing. The fine grain and its associated toughness are recovered again after subsequent heat treatment at the usual temperatures.

In tool steels employing large amounts of vanadium the fine grain size is relied upon for toughness at high hardness, while the carbide is effective in producing cutting qualities, abrasion resistance, and permissible high tempering temperatures.

See the article on the Welding of Metals in this Handbook for the welding of vanadium steels.

Constitution of Iron-Vanadium—The Constitution diagram of this binary system, important to a knowledge of the behavior of vanadium steels, will be found on page 403.

Structure of Iron-Carbon-Vanadium Alloys—No recent published data are available for annealed and quenched steels that are sufficiently extensive to yield diagrams similar to those in this Handbook for steels alloyed with manganese, chromium or molybdenum.

Uses and Properties of Carbon-Vanadium Steels—The principal constructional steel of this type has the following composition: C 0.45-0.55, Mn 0.70-0.95, V 0.15 (min.).

This steel is used for locomotive forgings such as axles, crank pins, connecting rods, piston rods. The forgings are usually normalized and tempered.

For automobile crankshafts, this steel is drop forged, normalized, restruck and die straightened at the normalizing temperature and is ready for machining without further heat treatment. These shafts maintain their dimensions without warping throughout machining operations as well as when in service in the motor because of practical freedom from internal stresses.

For large forgings of carbon-vanadium steel the following heat treatment is generally used: Normalize 1600-1650°F., air; temper 1100-1200°F., furnace or air.

The following mechanical properties are typical production values:

	5 in. dia.	9 in. dia.	13 in. dia.
Yield point, psi.....	72,000	65,000	63,000
Tensile strength, psi.....	110,000	97,000	95,000
Elongation, % in 2 in.....	25	24	23
Reduction of area, %.....	52	48	46

This steel responds well to quenching and tempering and has been used for such parts as forging dies, large piston rods, and shafting. Quenched, and tempered from

1000-1200°F., the physical properties obtainable from forgings of over 5 in. section are of the following order: Yield point, 75,000-100,000 psi.; tensile strength, 110,000-130,000 psi.; elongation in 2 in., over 20%; reduction of area, over 48%.

The transformation temperatures of a 0.50% carbon carbon-vanadium steel are:

Beginning	Ac ₁ Maximum	Ac ₃	Ar ₃ Beginning	Beginning	Ar ₁ Maximum
1385°F	1400	1490	1350	1275	1270

Carbon-vanadium steel castings have been used extensively for locomotive and heavy machinery parts such as main frames, driving wheel centers, crossheads, rolling mill coupling boxes, and gears. The following composition is typical: C 0.28-0.42, Si 0.25-0.50, Mn 0.75-1.00, V 0.15 min.

Normalized and tempered carbon-vanadium steel of about 0.35% carbon gave the following values:

Yield Point, psi.	Tensile Strength, psi.	Elong. % in 2 in.	Red. of Area, %	Izod, ft.-lb.
59,900	93,800	23.5	46.3	29.0
55,800	91,000	25.0	44.9	30.8
63,000	90,000	25.0	42.0	35.0*
62,300	93,400	24.5	47.8	20.8

*Double normalized and tempered.

A typical endurance limit based on material of 89,000-90,000 psi. tensile strength is 40,500 psi.

The heat treatments for the development of these properties normalize at 1600-1650°F.; temper 1050-1200°F.; sometimes double normalizing is employed, in which case the temperatures are 1775-1850°F. and 1575-1625°F.

Uses and Properties of Chromium-Vanadium Steels—The chromium-vanadium steels generally conform to S.A.E. specifications (6100 series) which are given in this Handbook under S.A.E. Steels.

S.A.E. Steels 6115, 6120, and 6125—These chromium-vanadium steels, and especially the first two grades, when specified within the carbon range of 0.12-0.20% are used for case hardened parts, such as automobile gears, camshafts, and piston pins. They give a hard, tough, strong case of high wear resisting quality which, due to the low rate of drop in the carbon content as the core is approached, is quite free from the tendency to flaking, powdering, or flowing under pressure.

A frequently used heat treatment procedure is as follows: Carburize at 1650-1700°F. and cool in the pots. Oil quench from 1600-1650°F. Water quench from 1475-1500°F. Temper at 375-425°F.

While this treatment gives the best properties in both case and core, many purposes are served by a single quench, which is carried out directly from the pot or after reheating to 1625°F. Chromium-vanadium steels are more applicable to single quenching than many of the other alloy steels, due to the fine grain in the case, even after the higher temperature necessary for a single quenching operation.

Steels 6120 and 6125 readily respond to cyanide hardening, and are so used for gears, bolts, washers, small stampings, and forgings. The nitrides formed are extremely fine and there is no tendency to develop the long needle-like structure, thus producing case toughness. The transition from the hard surface to the core is not abrupt, and even in long time cyaniding there is no danger of embrittlement of the core.

These chromium-vanadium steels are also used in boiler construction, super-heater tubes, pressure vessels, bolts, tubing for the chemical industry, and for welding rods. Plates and tubing of this steel will have a tensile strength of 80,000-100,000 psi. at room temperature and at 900-950°F. will have double the load-sustaining capacity of carbon steel at the same temperature.

A steel suitable for automotive ring gears and similar parts has the following composition: C 0.12-0.17, Ni 0.40-0.60, Cr 0.45-0.75, V 0.12-0.18. This steel gives freedom from warpage, a fine machine finish, and moderate core strength.

Steels 6125 and 6130—These steels are used for parts requiring high strength and toughness for such parts as automobile axles, steering arms, connecting rods, crankshafts; and for machine tool arbors, spindles, and shafting, and where it is necessary to machine after heat treatment. The following is the general heat treatment of forgings of this composition: Normalize 1600-1650°F., air; quench 1560-1600°F., water or brine; temper 1000-1120°F.

In the heat treated condition forgings have approximately the following properties: Yield point, 115,000-140,000 psi.; tensile strength, 135,000-160,000 psi.; elong. in 2 in., 20-17%; reduction of area, 65-60%; and Brinell hardness, 280-330.

Chromium-vanadium steel containing over 0.35% carbon is generally used in the oil hardened condition. The particular carbon range employed is influenced by the size of the part and the service to be met.

Steels 6135 and 6140—These steels are used in small bevel and spur gears, rocker arms, small tools, wrenches, and other semihard parts. They are also used for large forgings where high elastic strength combined with toughness and fatigue resistance are required, and internal stresses must be minimized such as Diesel engine crankshafts and connecting rods as well as hammer piston rods. For such large forgings, the heat treatment is commonly normalizing followed by tempering from 1000-1250°F.

The following is the general heat treatment for quenched and tempered parts: Normalize 1600-1650°F., air; quench 1560-1650°F., oil; temper, 500-1200°F. according to requirements and size.

The properties are approximately: Yield point, 210,000-75,000 psi.; tensile strength, 225,000-100,000 psi.; elong. in 2 in., 10-25%; reduction of area, 40-60%; and Brinell hardness number, 444-207.

The 6135 type of chromium-vanadium steel, usually with slightly higher chromium, is used for important parts of the equipment for manufacture of synthetic ammonia, notably the large catalyst chambers, because of its resistance to deterioration and ability to withstand high pressures at temperatures up to about 1000°F. This steel is also used for oil cracking stills subjected to high temperatures and pressures and certain types of mild corrosion. These parts, because of their large size, cannot be quenched, but the physical properties and grain refinement are obtained by normalizing and tempering or by annealing. Typical values are as follows:

	Normalized and Tempered	Quenched and Tempered
Yield point, psi.....	63,000- 70,000	75,000- 82,000
Tensile strength, psi.....	93,000-100,000	100,000-110,000
Elongation in 2 in., %.....	24-28	22-25
Reduction of area, %.....	50-56	55-62

Steels 6145 and 6150—These chromium-vanadium steels are used for highly stressed parts such as transmission gears. They have also proven to be ideal for all classes of springs, due to their high elastic limit and fatigue resisting qualities over a wide range of stresses. These steels have been used for many years for automotive chassis springs and valve springs, and are now being extensively used for locomotive and railway car springs. They are also standard for the welding of worn railway rails, providing a tough, wear resistant surface.

For gears and other highly stressed parts, such as shafting, the general heat treatment recommended is: Normalize 1600-1650°F., air; quench 1560-1625°F., oil; temper 450-1050°F. to a Brinell hardness number of 550-320, depending upon requirements.

The properties obtained are approximately:

Yield point, 250,000-125,000 psi.; tensile strength, 270,000-150,000 psi.; elong., 6-17%; reduction of area, 25-50%; and Brinell hardness number, 550-320.

The heat treatment for springs is as follows: Quench 1560-1625°F., oil; temper 850-1025°F. to a Brinell hardness number of 375-444. The properties are approximately: Yield point, 170,000-195,000 psi.; tensile strength, 180,000-215,000 psi.; elong. in 2 in., 14-10%; reduction of area, 40-28%.

The transformation temperatures of some of these chromium-vanadium steels are:

S.A.E. Steel No.	Ac ₁		Ac ₃	Ar ₃	Ar ₁	
	Beginning	Maximum			Beginning	Maximum
6115	1420	1435	1560	1550	1320	1300
6130	1410	1430	1490	1430	1315	1305
6150	1380	1415	1470	1305	1290

Uses and Properties of Manganese-Vanadium Steels.—There are three principal steels of this type, one developed primarily for normalized and tempered large forgings, such as locomotive driving axles, crank pins, piston rods, connecting rods and shafts, and similar heavy machinery forgings; the second for rolled plates, structural shapes, engine bolts, and rivets; the third for castings.

Forging—The composition for the forging grade is: C 0.27-0.34, Mn 1.45-1.75, V 0.15 min.

The following heat treatment is general: Normalize 1580-1630°F., air; temper 1150-1250°F., furnace or air.

Typical property values are as follows:

	Yield Point, psi.	Tensile Strength, psi.	Elong., % in 2 in.	Red. of Area, %
Connecting rod	77,800	101,250	28.0	65.6
Crank pin	81,000	104,500	26.0	61.6
Driving axle	74,800	99,000	25.0	59.8

An exceptionally high fatigue or endurance limit is obtained with this grade of steel and a representative value is a 0.55 ratio based on the tensile strength.

Small sections water quenched from 1550-1600°F. and tempered in the range of 500-1200°F. show the following properties: Yield point, psi., 115,000-210,000 psi.; tensile strength, 120,000-235,000 psi.; elong. 23-12% in 2 in.; reduction of area, 65-48%; and Brinell hardness number, 240-475.

The transformation temperatures of this manganese-vanadium composition are:

	Ac ₁		Ac ₃	Ar ₃	Ar ₁	
	Beginning	Maximum			Beginning	Maximum
1340°F.		1360	1420	1320	1125	1090

For the rolled manganese-vanadium steels (plates and shapes), three grades are specified as follows:

	Grade A	Grade B	Grade C
C max. %	0.18	0.18*	0.22
Mn max. %	1.35	1.45	1.55
Si %	0.15-0.30	0.15-0.30	0.15-0.30
P max. %	0.04	0.04	0.04
S max. %	0.05	0.05	0.05
V %	0.08-0.14	0.08-0.14	0.08-0.14
Tensile strength, psi.	70,000-85,000	80,000-95,000	90,000-105,000
Yield point, min., psi., for thicknesses up to 1 in.	50,000	55,000	60,000
Yield point, min., psi., for thicknesses over 1-1½ in.	48,000	53,000	58,000
Yield point, min., psi., for thicknesses over 1½-2 in.	45,000	50,000	55,000
Yield point, min., psi., for thicknesses over 2 in.	42,000	47,000
Elongation in 8 in., min., %	20	18	16
Elongation in 2 in., min., % for thicknesses over 1½ in.	28	25	22
Reduction of area, min., %	50	50	40

*0.20% C for sections over 2 in. in thickness.

The transformation temperatures of Grade B manganese-vanadium steel plate are:

	Ac ₁		Ac ₃	Ar ₃	Ar ₁	
	Beginning	Maximum			Beginning	Maximum
1320°F.		1360	1450	1430	1140	1110

Castings—This type is produced in two composition ranges, each containing about 0.10% vanadium. The remainder of the composition closely resembles that used in the common pearlitic or intermediate manganese steel castings. Vanadium produces an improvement in the microstructure and mechanical properties. It retards grain growth at the heat treatment temperatures and is accompanied by an absence of that microsegregation so common to pearlitic manganese cast steels, which is recognized as small martensitic areas under the microscope and productive of low and variable resistance to impact and poor machining qualities. The impact value of these manganese-vanadium steels is from 2-5 times that of similar steels without the vanadium. These cast steels are being used for locomotive and heavy machinery castings in the normalized and tempered condition. The typical compositions are as follows:

C	Si	Mn	V
0.35%	0.40%	1.40%	0.10%
0.30	0.40	1.70	0.10

Typical mechanical properties for the manganese-vanadium cast steels are as follows:

Yield Point, psi.	Tensile Strength, psi.	Elongation, % in 2 in.	Reduction of Area, %	Izod Value, ft.-lb.	
75,500	100,500	27.0	56.2	53.0	Normalized and tempered Double annealed
70,750	103,100	25.0	51.9	43.0	
69,400	93,450	31.0	61.1	61.0	
60,000	96,300	26.8	50.0	28.0	

Endurance limits of 46,000-52,000 psi. have been obtained over the range of tensile strengths giving an endurance ratio of 0.48.

Other Vanadium Steel Castings—While the steels just described are the principal ones produced, there are a number of other alloy steel casting compositions containing vanadium used for more or less special applications. Some of these compositions are as follows:

C	Mn	Si	Cr	Ni	Mo	V
0.30	0.80	0.40	1.00	0.10
0.30	0.50	0.30	1.00	0.15	0.10
0.30	0.60	0.40	0.50	1.30	0.10
0.35	1.50	0.40	0.15	0.10

Vanadium has proved beneficial in retaining shock resistance in copper-bearing steels as is evident from the following table of tests of manganese-copper-vanadium steel:

Composition, %					Heat Treatment, °F.			Yield	Tensile	Elong.	Red. of
C	Mn	Si	Cu	V	All in Air			Point,	Strength,	%	Area,
								psi.	psi.	2 in.	Izod,
											ft.-lb.
0.29	1.12	0.44	1.04	0.10	1650	1500	750	73,200	96,400	30.0	57.0

Ordinary alloy cast steels, when compositions or heat treatment or both are adjusted to produce high hardness and tensile strength, show a rapid decrease in impact value. Many engineers have taken but little cognizance of the impact strength of cast steels even when applied to types of service where high impact value affords a great measure of insurance against failure. The combination of high yield point, high tensile strength, and proportionately high impact resistance

of some harder vanadium cast steels in the normalized and tempered condition are shown in the following tabulation:

Type	C	Mn	Si	Mo	Cr	Cu	V
Mn-Cr-V	0.44	1.48	0.47	0.61	0.10
Mn-Cu-V	0.43	1.48	0.44	0.80	0.10
Mn-Mo-V (I)	0.45	1.53	0.48	0.16	0.10
Mn-Mo-V (II)	0.36	1.17	0.48	0.33	0.10

Type	Yield Point, psi.	Tensile Strength, psi.	Elongation, % in 2 in.	Reduction of Area, %	Izod Value, ft.-lb.
Mn-Cr-V	76,600	119,250	25.0	56.2	34.5
Mn-Cu-V	85,800	121,200	22.0	46.3	44.5
Mn-Mo-V (I)	83,900	128,900	20.5	35.0	30.3
Mn-Mo-V (II)	90,750	133,450	12.0	25.4	25.5

When design will permit mild quenching (oil), high yield strength and resistance to impact may be obtained in a cast chromium-molybdenum-vanadium steel originally developed for surface hardening by nitrogen. The properties of this steel are as follows:

C	Cr	% Mo	V	Yield Point, psi.	Tensile Strength, psi.	Elong., % in 2 in.	Reduction of Area, %	Izod, ft.-lb.
.19	2.35	0.37	0.27	138,350	152,850	15.0	46.0	40
				119,650	131,900	17.0	65.4	63

Alloy cast steels with higher vanadium content than described possess significant advantages with respect to mechanical properties that make them useful both at normal and at moderately elevated temperatures. In this class, chromium-vanadium, chromium-tungsten-vanadium, and chromium-molybdenum-vanadium steels have proved effective for steel mill rolls, piercing points for seamless tubes, and oil refinery castings.

After normalizing at 1650°F., water quenching from 1500°F. and tempering 650-1250°F., a 1 in. section gave the following properties: Yield point, 90,000-175,000 psi.; tensile strength, 100,000-200,000 psi.; elong. in 2 in. 26-6%; and reduction of area, 57-12%.

The following transformation temperatures are for the 0.35% carbon steel listed above:

Beginning	Ac ₁	Maximum	Ac ₃	Ar ₃	Beginning	Ar ₁	Maximum
1350°F.		1385	1480	1340	1215		1190

Nickel-Vanadium Steel Castings—This steel is used only in the form of castings. A typical composition of nickel-vanadium cast steel is: C 0.28, Mn 1.00, Ni 1.50, and V 0.10. The carbon content is usually in the range of 0.26-0.33%.

After normalizing and tempering, this steel gives the following average properties:

Yield Point, psi.	Tensile Strength, psi.	Elong., % in 2 in.	Red. of Area, %	Izod, ft.-lb.	
68,000	93,850	28.0	53.8	47.8	} Normalized and tempered Double annealed
69,500	98,000	27.5	55.9	55.9	
70,500	96,500	28.0	59.9	59.5	
62,000	95,000	25.0	45.0	40.0	

The endurance limit of this cast steel is typified by a rotating beam method value of 44,000 psi. obtained on coupon bars having a tensile strength of 91,450 psi., thus giving an endurance ratio of 0.482.

One-inch sections quenched from 1500°F. after normalizing at 1775°F. show, over the tempering temperature range of 750-1250°F., the following properties: Yield point, 90,000-120,000 psi.; tensile strength, 100,000-145,000 psi.; elong. in 2 in., 25-14%; reduction of area, 58-43%.

The transformation temperatures for this steel are as follows:

Ac_1		Ac_3	Ar_3	Ar_1	
Beginning	Maximum			Beginning	Maximum
1315°F.	1345	1480	1320	1140	1115

Low temperature impact test results compared with plain carbon steel, are shown in Fig. 1. These tests are on Charpy specimens with keyhole notch and minimum metal section of 5 x 10 mm.

Fig. 1—Effect of temperature on impact strength of vanadium and carbon cast steels.

Uses and Properties of Manganese-Chromium-Vanadium Steel—This steel is used for small forgings such as automobile crankshafts, connecting rods and steering arms. The composition is as follows: C 0.15-0.50, Mn 1.00-1.60, Cr 0.30-0.65, V 0.06-0.12.

One-inch rounds quenched from 1550°F. into water show, over the tempering range of 400-1250°F., the following mechanical properties: Yield point, 95,000-210,000 psi.; tensile strength, 105,000-275,000 psi.; elong. in 2 in., 27-12%; and reduction of area, 65-40%.

An automobile crankshaft in the normalized condition gave the following results: Yield point, 72,000 psi.; tensile 111,000 psi.; elong. in 2 in., 20%; and reduction of area 55%.

The transformations of the manganese-chromium-vanadium steel of 0.40 carbon are:

Ac_1		Ac_3	Ar_3	Ar_1	
Beginning	Maximum			Beginning	Maximum
1360°F.	1380	1510	1345	1240	1230

Silicon-Vanadium Spring Steel—This type of vanadium steel is used principally for helical springs made from bars of ½ in. and over in diameter or thickness, such as railroad car and draft springs. It has high strength properties in tension and torsion, combined with toughness, and good surface condition. As compared with

carbon spring steel, it can be safely worked to about 15% higher stresses without danger of settling.

The composition specification for this steel is: C 0.88-0.98, Mn 0.45-0.65, Si 0.50-0.75, V 0.15 min.

Quenched in oil from 1600°F. (the usual range is 1575-1625°F.) 1 in. rounds, tempered 750-1100°F., gave the following properties: Yield point, 165,000-245,000 psi.; tensile strength, 185,000-270,000 psi.; elong. in 2 in., 14-7%; reduction of area, 35-17%.

Vanadium Nitriding Steels—Vanadium steel parts have been successfully employed in applications requiring the high surface hardness produced by nitrogenous gas at temperatures of 800-1200°F. Vanadium is present in the familiar aluminum-chromium type of nitriding steel in amounts up to about 0.10%.

Alloy steels of the S.A.E. 6100 type, particularly the 0.20 and 0.50 carbon grades, have been used to a limited extent where a maximum surface hardness of 750-800 Vickers suffices. A steel containing approximately 0.25% carbon, 1.50 chromium, and 0.60 vanadium is capable of producing a nitrided case hardness of approximately 850 Vickers. Where higher core hardness and tensile strength with both case ductility and good case hardness are desirable, a steel containing nominally 0.18% carbon, 2.75 chromium, 0.25 vanadium, and 0.50 molybdenum is now available for nitriding, particularly, in the cast condition. A case hardness of 900 Vickers is obtainable with this steel along with good combinations of yield point and impact strength in the core. For higher case hardness, approximately 1050 Vickers, a modification of this chromium-molybdenum-vanadium steel with 4.25% chromium may be employed.

The process has also been applied to a tool steel containing approximately 1.50% carbon, 13.00 chromium, 1.00 vanadium, and 1.00 molybdenum in parts requiring the presence of a hard core (500-600 Brinell) to support the nitrided surface. When quenched from 2050°F. this steel is austenitic, but develops high secondary hardness upon subsequent exposure to a temperature of 950-1050°F. After nitriding, the surface hardness exceeds 1000 Vickers.

Vanadium Tool Steels—Vanadium is an important element in a large number of tool steels. In the low alloy steels the amounts range from 0.15-0.65%, whereas in high speed steel and other high alloy tool steels the quantity usually varies from 0.50-2.50%. In some instances approximately 4% vanadium has been used but at the same time approximately 1.25% carbon has also been introduced.

In the carbon-vanadium steels, the depth of penetration of full hardness is moderate (neither shallow nor deep) and uniform. The vanadium also results in a wider permissible hardening range (for carbon-vanadium steels up to 1600°F.) without likelihood of grain coarsening, thus permitting effective hardening of heavier sections and of tools of variable section without the development of brittleness.

The inclusion of vanadium in the composition of tool steels is generally regarded as productive of stronger and tougher tools that hold their cutting edges better than do tools of steels not containing vanadium.

Details on the heat treatments, compositions, and applications for tool steels and specific classes of tools are given in the heat treating section of this Handbook. As vanadium tool steels are covered, the reader is referred to those articles for additional information.

Aging in Iron and Steel

By S. Epstein* and H. L. Miller†

Definition of Aging—Aging is the spontaneous change in the properties of iron or steel which occurs at atmospheric temperature, or moderately elevated temperature, after a final heat treatment or final cold working operation. These changes proceed relatively slowly at room temperature but at an accelerated rate as the aging temperature is raised. This indicates that aging is a manifestation of a trend toward equilibrium and away from some unstable condition set up by the final operation performed upon the steel (cooling or cold deformation). Aging may result in an increase in hardness and strength, a loss in ductility and impact resistance, the reappearance after cold working of a sharply defined yield point in the stress-strain curve of a tensile test, an increase in coercive force and similar changes in other properties.

Aging is generally assumed to be caused by the disintegration of a supersaturated solid solution. In a system in which the solid solubility of the solute falls sharply with temperature, the solute may be retained in supersaturated solution by quenching, but it will tend to precipitate out on standing. Such incipient or complete precipitation (more probably incipient) is considered to be the cause of the observed aging phenomena in iron and steel.

Since carbon has a much higher solubility in austenite than in ferrite, the decomposition of austenite to ferrite leads to a precipitation of carbon and to hardening. Indeed, such precipitation may be the chief cause for the high hardness attained by quenched high carbon steel; thus the hardening of carbon steel by quenching may also involve an aging phenomenon. However, the term aging is generally used only with reference to precipitation phenomena in ferrite itself, below the A_1 critical temperature. Such aging occurs in several alloys with iron, as in the iron-copper alloys. However, this article will deal only with aging effects in ordinary iron and steel and not in special iron alloy systems.

Interest in aging has increased since it has become apparent that the "blue heat phenomena" in iron and steel are associated with aging, and since it has been found that virtually nonaging steels can be produced by drastic deoxidation, as with aluminum or titanium, followed by the proper heat treatment.

Hayes and Griffis¹² have reported that the kind of heat treatment which will give a material essentially free from strain aging, consists in heating preferably above the critical range with relatively rapid cooling and then reheating in the neighborhood of the A_1 temperature and slowly cooling. They report they have

found the above heat treatment, when properly carried out, will stabilize materials deoxidized with a wider range of deoxidation treatments than can be produced by slow cooling only, from temperatures either above or below the A_1 point. In general, the less drastic the deoxidation, the more carefully the heat treatment has to be applied to produce a stable material.

Elements Which May Give Rise to Aging Effects—The following elements are found in ordinary iron and steel, C, Mn, Si, P, S, O, and N. Of these, C and N, have an appreciable solubility in ferrite directly below the A_1 temperature and

Fig. 1—Change in solubility with temperature of C, O, and N in fairly pure ferrite.^{1, 2, 3}

much lower solubility at room temperature. Thus, if the latter solubility is less than

*Metallurgist, Bethlehem Steel Co., Bethlehem, Pa.

Prepared for the Subcommittee on Aging. The membership of the subcommittee was as follows: E. S. Davenport, chairman; J. J. Bowden, H. K. Ihrig, and R. S. Burns.

the amount of the element present, precipitation and aging phenomena can occur. Curves for the change in solubility with temperature of C, O₂, and N₂ are shown in Fig. 1. All of these solubility curves may be of uncertain accuracy and should therefore be regarded merely as approximations.

Si and P have similar solubility curves, but their solubility in ferrite at room temperature is much higher than that ordinarily present in iron and steel, so that these elements do not give rise to precipitation effects, although they may influence the aging phenomena by causing C, O₂, or N₂ to precipitate out more readily. Mn also has a higher solubility in ferrite than that ordinarily present so it should not of itself give precipitation effects. S is present mainly as MnS inclusions and is not considered to give rise to precipitation effects. However, it is known that MnS has a slight solubility in the solid state and it may therefore have an influence on strain aging.

C and N₂ have been definitely shown to give rise to precipitation or aging effects when present in amounts ordinarily found in low carbon iron and steel.⁹ It will be observed in Fig. 1 that the room temperature solubility of N₂ in ferrite is not more than 0.001%, so that precipitation effects due to N₂ can occur in steel containing more than this amount. Open hearth steel generally contains about 0.004-0.006% N₂, while Bessemer steel may contain over 0.020% N₂; the precipitated N₂ in such steels can be observed under the microscope as nitride needles.

There is still some doubt whether O₂, by itself, is an important cause of aging in iron and steel. Several investigators^{4, 5, 6, 7} have found that iron or steel containing O₂ in amounts such as would ordinarily be found dissolved in such materials, say up to 0.035%, do not show quench aging effects in the absence of C and N₂, although they do show strain aging effects.^{24, 25} Quench aging is the term used to denote the changes which take place in steel following a final operation consisting of fairly rapid cooling from an elevated temperature; strain aging is the term applied to the changes which take place in steel when the final operation consists of cold working; these two categories of aging phenomena will be discussed more fully below. Yensen and Ziegler have reported magnetic aging effects apparently due to O₂ in very pure iron practically free from C and N₂.

This seems to contradict the fact that strongly deoxidized steel is nonaging. The explanation may be that although O₂ does not of itself give rise to aging effects it may cause C and N₂ to do so. That is, O₂ may greatly reduce the solubility of C and N₂ in ferrite so that its presence in solution causes aging. When the O₂ is removed or "fixed" by a strong deoxidizer like Al, however, the room temperature solubility of C and N₂ may be increased thereby and precipitation aging may thus be greatly reduced. Al or Ti would also "fix" the N₂ itself, and Ti would tend to "fix" the C, so that after such strong deoxidation, C and N₂ would not go in and out of solution and hence would not give rise to precipitation effects.

Quench Aging and Overstrain Aging—Overstrain, such as strain above the elastic limit, frequently plays such a prominent part in aging that it has been found convenient to differentiate between aging which results merely from heat treatment and that which occurs after straining or cold working. The former has been designated quench aging and the latter overstrain aging. In overstrain aging a high degree of supersaturation of the solute does not appear to be necessary, but precipitation is thought to occur because overstraining causes local supersaturation along slip planes. In general a steel which shows quench aging will also show strain aging. Low carbon iron, however (C 0.004%), which shows no quench aging still shows overstrain aging effects.⁷

Fig. 2—Quench aging of 0.08% carbon steel. Hardness after quenching from 1325°F. and aging at indicated temperatures³⁰.

room temperature, but the maximum hardness attained is lower. After the maximum hardness is reached further elevated temperature aging causes a decrease in hardness (Fig. 2). This is sometimes called "overaging".

Quench Aging—In quench aging above room temperature the hardness increases more rapidly than at lower temperatures. In general a steel which shows quench aging will also show strain aging. Low carbon iron, however (C 0.004%), which shows no quench aging still shows overstrain aging effects.⁷

Quench Aging—In quench aging above room temperature the hardness increases more rapidly than at

The magnitude of the quench aging effects which may occur in low carbon alloys is illustrated by the following results from Masing and Koch.⁸

C %	Mn %	P %	Si %	Brinell Hardness	
				Directly After Quenching from 1300°F.	On Aging 44 hr. at 125°F. after Quenching
0.028	0.39	0.025	0.003	102	163
0.044	0.44	0.036	0.005	128	185

In a series of Fe-C alloys made up from electrolytic iron without Mn and with 0.02-0.03% P; 0.007-0.008% Si; and under 0.001% S, they obtained the following:

	Carbon, %					
	0.019	0.033	0.043	0.063	0.087	0.166
Brinell Hardness						
Directly after quenching from 1300°F.....	85	79	89	123	127	136
On aging 8 days at 125°F. after quenching.....	92	80	101	207	170	194
Increase in Brinell Hardness.....	7	1	12	84	43	58

No appreciable age hardening occurred in alloys below about 0.035%C. The age hardening effect reached a maximum in the 0.063%C specimen.

The degree of quench aging is greatly reduced by strongly deoxidizing the steel, particularly by killing with aluminum. This is indicated in Fig. 3.

Strain Aging—Straining may result in two effects, first the increase in hardness which accompanies cold working in even the purest single phase metal, and second the increase in hardness by the precipitation or dispersion of another phase induced by the straining. Strain aging is usually determined by measuring the change in hardness (or impact resistance) with time after straining.

Fig. 3—Reduction in the aging effect as a result of strong deoxidation⁹. The Si killed steel contained about 0.15% Si and the Al killed steel an equal amount of Si with about 0.04% Al. The maximum aging effect occurred at about 0.05%C.

Fig. 4—Increase in hardness with cold work of Bessemer, Duplex, open hearth and Izett steel¹⁰. The first three are aging steels and the last is an Al killed nonaging steel. There was a lower rate of hardness increase with cold work in the nonaging steel.

	C%	Mn%	S%	P%	Si%	Al%
Bessemer	0.08	0.47	0.035	0.102
Duplex	0.22	0.54	0.030	0.017
Open
Hearth	0.21	0.40	0.035	0.010
Izett	0.13	0.58	0.04	0.05

However, some precipitation may occur during the straining itself. Probably it is for this reason that cold working produces a greater increase in hardness in "aging" than in "nonaging" steels. This is indicated in Fig. 4. No tests were made between 0 and 5% compression. Between 0 and 2% deformation it is frequently observed that no hardening but an actual slight softening takes place. This phenomenon appears to be analogous to a slight softening which is sometimes observed in the early stage of quench aging designated as the incubation period.

In general, the changes in hardness on strain aging are somewhat smaller than on quench aging although the degree of straining influences this to some extent, the greater the degree of straining (within limits) the greater the age hardening. This

is indicated in the following data from Harrison.¹¹ His steel had a composition of C 0.22, Mn 0.37, Si 0.10, S 0.040, and P 0.20%. The Brinell hardness was 118 as annealed from 1700°F.

	As Quenched or Rolled or Both	Aged 2 Months	Increase Hardness Due to Aging	
Quenched in water from 1250°F., Brinell hardness...	151	181	30	Quench aging
Cold rolled 10%, Brinell hardness.....	155	166	11	Strain aging
Quenched in water from 1250°F. and then cold rolled 10%, Brinell hardness.....	183	221	38	Quench and strain aging

On the other hand, the embrittlement induced by strain aging may be greater than that resulting from quench aging. Quench aging lowers the impact resistance but it seldom results in actual brittleness¹ whereas strain aging may result in a brittle fracture. This is indicated in Fig. 5, showing that the impact resistance at room temperature fell to very low values on cold working aging steels (giving brittle fractures) whereas the "nonaging" steel retained high values and a ductile fracture. This is directly after cold working. The impact resistance may be further lowered by aging, particularly accelerated aging, the maximum lowering

Fig. 5—Effect of cold work on impact resistance of aging and nonaging steels¹⁰. Armco iron, duplex, open hearth, and Bessemer steel are aging; Izett is nonaging.

somewhat ambiguous, but there is no doubt that coarse grained steels are more susceptible to embrittlement (brittle fracture) after straining and aging than fine grained steels.

Fig. 6—Jogged stress-strain curve in annealed mild steel sheet¹⁴.

stresses.¹⁴ Hayes and Griffs¹⁵ have recently suggested that the prior cold working may bring the material to a state where the rate of work hardening is high enough to prevent any decrease in load with further deformation.

occurring, on heating about $\frac{1}{2}$ hr. at 500°F.¹² The embrittlement after cold working may be increased on heating a minute or two at 850°F. as in hot dip galvanizing.¹⁰

It should be stated that the relatively nonaging Izett steel in Fig. 5, was finer grained than the others, so that a part of its immunity to embrittlement was probably due to its finer grain. Daniloff¹² has demonstrated that as measured by hardness tests coarse grained steels show greater aging effects both after quenching and aging and after deformation and aging than fine grained steels. As measured by impact tests his results were

A most interesting and not fully understood phenomenon in iron and mild steel is the jog in the stress-strain curve at the yield point which causes the drop in the beam in a tension test. In a previously strained specimen this is not present and a rounded stress-strain curve is obtained instead, with no sharply defined proportional limit. This is shown in Fig. 6. The disappearance of the jog and the rounding of the stress-strain curve have usually been attributed to a loss of elasticity due to the setting up of internal

On aging after cold working the jogged type of stress-strain curve is again obtained in ordinary mild steel such as sheet. In nonaging steel, however, as in the "stabilized" material described by Hayes and Griffis, this does not occur and a rounded curve is still obtained after aging. This is illustrated in Fig. 7.

Fettweiss¹⁷ suggested in 1919 that the increase in tensile strength which is observed in the region of about 400°F. (the blue heat region) is caused by aging, the explanation being that the test specimen increases in hardness due to cold work and aging while it is being deformed in testing. Fettweiss' hypothesis has received striking confirmation in tensile tests of the recently produced Izett type nonaging structural steel and in the stabilized sheet steel, in the blue heat region.^{18, 19} Neither of these nonaging materials showed so pronounced an increase in strength in the blue heat region as aging material. Thus the "blue heat phenomenon" is obviously an aging effect.

Such results by Kenyon on stabilized sheet and on ordinary aging sheet are shown in Fig. 8 and 9. The stepped stress-strain curves of the aging material tested in the blue heat region, as shown in Fig. 9 are characteristic. Kenyon¹⁰ has stated that a tensile test in the blue heat region is one of the simplest ways of distinguishing between aging and nonaging material.

The blue heat region is frequently referred to as the blue brittle region. This term is accurate in so far as the ductility in a tension test at these temperatures is appreciably lower. Likewise after deformation at these temperatures, or on deformation at room temperature followed by heating at those temperatures, there

Fig. 7—Return of jogged stress-strain curve on aging after straining in ordinary mild steel. Retention of smooth rounded curve after aging in stabilized or nonaging material¹⁸. Both materials rolled 1% before aging. Typical compositions of stabilized or nonaging material strongly deoxidized with Al and Ti

C%	Mn%	P%	S%	Si%	Ti%	Al%
0.05	0.03	0.005	0.019	0.067	0.042
0.042	0.47	0.011	0.014	0.073	0.058	0.037

Fig. 8—Effect of testing temperature on tensile strength of ordinary mild steel and of stabilized sheet¹⁰. The stabilized material gives almost no indication of the blue heat phenomenon. The ductility in a tension test of the stabilized material in the blue heat region is considerably higher than of ordinary aging mild steel sheet.

is a marked drop in impact resistance on testing at room temperature. However, there is no brittleness under impact in the ordinarily stated blue heat region at about 400°F. As a matter of fact as indicated in Fig. 5, the impact resistance on testing at these temperatures is nearly at a maximum.

It is true that at temperatures considerably above the blue heat region a minimum in the impact resistance-temperature curve does occur. This is shown in Fig. 10. The minimum is assumed to be due to an aging effect, that is, it is generally held that at the high speed of fracture in a dynamic impact test any aging (hardening) during the instant of fracturing can only occur at the higher temperature at which this reaction takes place rapidly. At lower temperatures, precipitation during a dynamic impact test cannot occur rapidly enough to cause hardening and hence there is no lowering of the impact resistance. There appear to be no data to indicate whether nonaging steel shows a less pronounced minimum in the impact resistance-temperature curve than aging steel.

Oddly enough, at approximately the same temperature as the minimum in the

impact resistance-temperature curve, a minimum in the ductility in a tension test also occurs. This has been termed by Freeman and Quick²¹ as the "secondary low ductile range." The severity of the "secondary low ductility" varies greatly in different steels. Although it appears to be decidedly affected by the manner of deoxidation of the steel, it is rather doubtful that secondary low ductility is mainly a precipitation or aging effect. Shapiro²² has indicated that it may be connected

Fig. 9—Stress-strain curves of ordinary mild steel sheet and stabilized sheet tested at various temperatures. The "stepped" stress-strain curve and the higher tensile strength of the ordinary sheet in the blue heat region is characteristic. These features are absent in the stabilized sheet.

which leaves the steel in an ideal condition for strain aging. Unless the material is promptly fabricated, the resulting increase in hardness and corresponding loss in ductility due to aging may constitute the difference between success and failure in the particular application involved.

The jog in the stress-strain curve at the yield point in a tension test manifests itself in the drawing and stamping of sheet as "stretcher strains"²³ giving an undesirable roughening of the surface. The jog is a characteristic of iron and steel in the soft annealed condition and can be eliminated by slight deformation as in the final "skin rolling" given the annealed sheet for this purpose and for straightening.¹⁸ In aging material the jog may return with time so that after leaving the steel mill and storing in the customer's plant the sheet may regain the tendency to stretcher strain. This does not occur in drastically deoxidized nonaging sheet. Such killed steel sheet is also more uniform from edge to center than rimming steel and apparently gives satisfactory drawing properties.

Cold deformation of structural steel, particularly when followed by reheating as in galvanizing, may lead to decided embrittlement. This is much less marked in aluminum killed nonaging steel. The benefits of such steel in overcoming embrittlement become decided only after normalizing, and not in the as rolled condition. Apparently the grain refinement which results from normalizing the fine grained type aluminum killed steel plays an important part in overcoming embrittlement. A punched rivet hole in a thick structural member provides a severe condition which may cause embrittlement even under slow bending.¹⁹

with the rate of recrystallization at this temperature during and after deformation, which rate may, of course, differ according to the degree of deoxidation, grain size, and rate of cooling of the steel.

Practical Aspects—

In practice the effects of strain aging are possibly of greater importance than those of quench aging. This is particularly true in the manufacture of low carbon sheet and strip steel for stamping and deep drawing; the final mill operation on this product is frequently a light "skin pass" or temper rolling

Fig. 10—Static and dynamic notched bar tests at various temperatures with annealed and with cold worked mild steel²⁰. On slow bending the energy absorption is at a minimum in the blue heat region, but in the impact test the minimum in energy absorption occurs at a considerably higher temperature.

In Germany, embrittlement failures in boiler plate have been attributed in part to the aging of strained areas about rivet holes and the use of nonaging steel for boilers has been advocated.¹²

Two probable instances of quench aging in which straining plays no part are temper brittleness, and the galvanizing embrittlement of malleable cast iron.

Temper brittleness is a fall in impact resistance in hardened medium carbon structural steel which occurs if the steel is slowly cooled after tempering but not if it is rapidly cooled after tempering. It was first noticed in nickel-chromium steel but has recently been observed also in carbon steel.¹⁴ Temper brittleness is no doubt a precipitation or aging effect. As with the other aging phenomena, it appears to be less pronounced in strongly deoxidized steel.^{15, 16} Temper brittleness appears to be more pronounced in steel with higher manganese and chromium, while molybdenum is known to reduce it.

Malleable cast iron may be decidedly embrittled by heating to 850°F. as in galvanizing. Marshall¹⁷ has shown that such embrittlement may be overcome by heating the castings to 1200°F. and water quenching, before galvanizing. Although the mechanism of this immunizing treatment is by no means understood,¹⁸ galvanizing embrittlement of malleable iron may perhaps be an aging effect; chemical composition of the iron, particularly the phosphorus and silicon content, also plays an important part in galvanizing embrittlement as shown by Bean.¹⁹

The prolonged annealing and slow cooling of malleable iron may possibly make it more susceptible to subsequent embrittlement by galvanizing. The following data from Harrison¹¹ point to an apparently analogous effect in steel, the more slowly cooled specimen being more susceptible to subsequent embrittlement in quench aging than the more rapidly cooled specimen. Somewhat similarly, in the case of temper brittleness in steel, it has been found that embrittlement occurs even on rapid quenching after tempering (ordinarily in temper brittle steel, embrittlement only occurs on slow cooling from the tempering temperature) if the steel is held for a long time at the tempering temperature.²⁴

Effect of Cooling Rate from 1650°F. Before Quenching from 1250°F.,
on Quench Aging (Harrison¹¹)

Air cooled from 1650°F.....	130	190 + 60		100	34 — 66	
Slowly cooled in furnace from 1650°F.	124	192 + 68		94	6 — 88	

The galvanizing embrittlement in malleable iron differs from that of the other cases mentioned in that the fracture is intercrystalline.²⁰ Possibly the dispersion effects occur in the grain boundaries as in carbide precipitation in 18-8 stainless steel. Ordinarily in quench aging and strain aging of mild steel the dispersion effects take place throughout the grain and on the slip planes; fracture is mainly transcrystalline.

Aging steels, since they harden and become embrittled more readily under cold work than nonaging steel, machine more easily; the chips become brittle under the action of the cutting tool and break off. For this reason, Bessemer steel makes a freer cutting screw stock than open hearth steel, the higher N₂ and O₂ in Bessemer steel probably promoting aging.²⁰ Because coarser grained steels age more readily than fine grained steels, they machine more readily. In general, fine grain and nonaging characteristics go together, both being caused by strong deoxidation.

Nonaging steels are tougher than aging steels. They have greater damping capacity and Foppl²¹ has indicated that on account of this they are less sensitive to notch effects in fatigue tests below the endurance limit. This is also indicated by the recent work of Brophy.²² Likewise since they do not harden so readily under cold work they are better able to withstand occasional overstresses considerably above the endurance limit, without fatigue failure. That is, they have the ability to withstand considerable cold work and inelastic action without starting a crack. This property has been termed by Moore as "crackless plasticity."²³

Mechanism of Aging—The exact stage of precipitation at which hardening takes place is not clearly understood; it may be complete precipitation of molecules or particles of the excess constituent or a stage between precipitation and solution; the stage of dispersion for maximum hardening may be somewhat different than for maximum embrittlement. Dean¹⁸ in discussing Van Wert's paper has even suggested that blue brittleness is not due to precipitation of iron nitride but to incipient solution.

Fig. 11.—Upper block—Quench aging of electrolytic iron and of 0.27% aluminum steel at 70°F. Note wide disparity in degree of age hardening. Lower block—Quench aging of O₂ saturated electrolytic iron at 70°F. and H₂ purified electrolytic iron at 105°F. Note absence of significant age hardening.

Fig. 12.—Upper block—Hardness of O₂ saturated electrolytic iron and H₂ purified electrolytic iron as strain aged at 105°F. pre-aged before cold deformation. Lower block—Hardness of non-aging steel and rimming basic open hearth steel as strain aged at 105°F.; also 0.27% aluminum steel as strain aged at 70°F. All pre-aged before cold deformation.

As has been stated, there is equal uncertainty as to which element C, O₂, or N₂ is mainly responsible for aging. The fact that drastic deoxidation reduces aging might indicate that O₂ is the main factor. However, in the amounts present in ordinary steel O₂ does not give rise to marked quench aging effects in the absence of C and N₂, although it appears to cause some strain aging effects.^{20, 21} Possibly the part of O₂ in quench aging (somewhat similar to that of P) is to change the solubility of C and possibly of N₂ in ferrite.

In studying the embrittlement of structural steel in galvanizing²² the evidence pointed to N₂, particularly in the presence of P as a cause of aging. Steels in which strain lines can be revealed by Fry etching have been considered more susceptible to aging embrittlement²³ and apparently the strain lines are mainly revealed because of the precipitation of N₂.²⁴ P probably contributes to aging and

embrittlement through its general effect in lowering the impact resistance and in altering the solubility of C and N, in ferrite. Precipitation and aging appear to occur more readily in coarse grain steel, although stretcher strains appear more prominently in fine grain steel. Similarly, it has been observed that precipitation of carbides occurs more readily in coarse grained 18-8 stainless steel than in fine grained 18-8.²⁸

Davenport and Bain²⁹ have recently concluded that quench aging in commercial low carbon steels is mainly due to carbon, while strain aging is mainly due to oxygen. Electrolytic iron high in oxygen and low carbon steel low in oxygen were quench aged as shown in Fig. 11. The effect of the carbon on the hardness is strikingly shown as well as the absence of effect of the oxygen.

Fig. 12 shows the effect of strain aging of low and high oxygen steels as prepared before cold working. The effect of the oxygen content is marked while the carbon seems to have little if any effect on this type of aging.

S. A. E. Steel Specifications*

A numerical index system is used to identify the compositions of the S.A.E. steels that are partially descriptive of the composition of material covered by such numbers. The first digit indicates the type to which the steel belongs; thus "1-" indicates a carbon steel; "2-" a nickel steel, and "3-" a nickel chromium steel. In the case of the simple alloy steels the second digit generally indicates the approximate percentage of the predominant alloying element. Usually the last two or three digits indicate the average carbon content in "points", or hundredths of 1%. Thus "2340" indicates a nickel steel of approximately 3% nickel (3.25-3.75) and 0.40% carbon (0.35-0.45); and "71360" indicates a tungsten steel of about 13% tungsten (12-15) and 0.60% carbon (0.50-0.70).

In some instances, in order to avoid confusion it has been found necessary to depart from this system of identifying the approximate alloy composition of a steel by varying the second and third digits of the number. An instance of such departure is the steel numbers selected for several of the corrosion and heat resisting alloys.

The basic numerals for the various types of S.A.E. steel are:

Type of Steel	Numerals (and Digits)
Carbon Steels	1xxx
Plain Carbon	10xx
Free Cutting (Screw Stock)	11xx
Free Cutting, Manganese	X13xx
High Manganese	T13xx
Nickel Steels	2xxx
0.50% Nickel	20xx
1.50% Nickel	21xx
3.50% Nickel	23xx
5.00% Nickel	25xx
Nickel Chromium Steels	3xxx
1.25% Nickel, 0.60% Chromium	31xx
1.75% Nickel, 1.00% Chromium	32xx
3.50% Nickel, 1.50% Chromium	33xx
3.00% Nickel, 0.80% Chromium	34xx
Corrosion and Heat Resisting Steels	30xxx
Molybdenum Steels	4xxx
Chromium	41xx
Chromium Nickel	43xx
Nickel	46xx and 48xx
Chromium Steels	5xxx
Low Chromium	51xx
Medium Chromium	52xxx
Corrosion and Heat Resisting	51xxx
Chromium Vanadium Steels	6xxx
Tungsten Steels	7xxx and 7xxx
Silicon Manganese Steels	9xxx

Prefixes

The prefix "X" is used in several instances to denote variations in the range of manganese, sulphur or chromium.

The prefix "T" is used with the Manganese Steels (1300 Series) to avoid confusion with steels of somewhat different manganese range that have been identified by the same numerals but without the prefix.

Carbon Steels

S.A.E. No.	Carbon Range	Manganese Range	Phosphorus Max.	Sulphur Max.

Notes for Tables of Chemical Composition

Note (a). Silicon range of all S.A.E. basic open hearth alloy steels shall be 0.15-0.30%. For electric furnace alloy steels and acid open hearth alloy steels, the silicon content shall be 0.15% min.

Note (b). Phosphorus and sulphur in all S.A.E. nickel steels, nickel-chromium steels, molybdenum steels and silicon-manganese steels shall be 0.040% max. and 0.050% max. respectively.

Note (c). Phosphorus in all S.A.E. chromium-vanadium steels shall be 0.040% max. except in No. 6195, which shall be 0.030% max. Sulphur in all S.A.E. chromium-vanadium steels shall be 0.050% max. except in No. 6195, which shall be 0.035% max.

Note (d). Phosphorus and sulphur in all S.A.E. tungsten steels shall be 0.035% and 0.040% max. respectively.

Note (e). Silicon shall be 0.50% max. except in alloys 30905 and 30915, which may be 0.75% max. Phosphorus shall be 0.030% max. in all corrosion and heat resisting alloys. Sulphur shall be 0.030% max. in all except in the free cutting alloy X51410, which shall be in the range 0.15-0.30%.

*No specified composition limits within the above ranges may be placed on these Types, except carbon may be specified to a four point range within the above limits.

Where definite carbon content .11 or under is specified for Types 302, 305 and 307, the price of Types 304, 306 and 308 respectively apply.

xIn these types manufacturers may accept specifications and furnish material with a guaranteed carbon content of .08 maximum.

Issued by the American Iron and Steel Institute, New York.

Cast Iron

By Hyman Bornstein* and J. W. Bolton†

I—Definitions and Commercial Classification—Cast irons are alloys of iron containing so much carbon that, as cast, they usually are not appreciably malleable at any temperature. (See below the paragraph on "Graphitic Steels".) Usually from 1.7-4.5% carbon is present and in most cases an important percentage of silicon. Because of the low melting point, fluidity, and simplicity of melting and casting practices, cast irons are readily made into useful shapes through casting processes and by machine cutting operations.

All cast irons are eutectiferous alloys and are classified as follows:

1. Pig iron
2. White cast iron
3. Malleable cast iron
4. Gray cast iron

Pig Iron—Pig iron is the product of the blast furnace and is made by the reduction of iron ore. With the exception of direct metal, pig iron is either remelted and cast (producing gray and white irons), or it is refined in the steel making processes.

(Some special pig irons are blast furnace products diluted in carbon and silicon content by the addition of molten steel to the molten blast furnace product.)

White Cast Iron—White cast iron contains carbon in the combined form. The presence of cementite or iron carbide (Fe_3C) makes this metal hard and brittle. White iron may be further classed according to the process. Chilled white cast iron is produced by casting the iron against metal chills. Such iron when cast in a sand mold may be gray iron, but the chills cause rapid cooling, thus forming cementite. White cast iron for malleable irons may be produced by adjusting the composition; a low silicon and carbon content produces a white or cementite fracture.

Beside chilled irons and white irons for malleable cast iron manufacture, irons white throughout as cast are used for special purposes, particularly for resistance to wear and abrasion. To get maximum hardness, alloys are usually incorporated—both to promote the formation of the cementite and to increase the hardness of the matrix. (See Section VII, Alloy Cast Irons, p. 626.) Special white iron rods are used for welding white iron layers onto various ferrous metals. The very high (25% and up) chromium cast irons, used for their corrosion resistance are white irons, properly speaking,

Fig. 1—Sectional view of a cupola (Dr. Moldenke).

but are little harder than some gray irons.

Malleable Cast Iron—This term is applied to castings in which all the combined carbon in a special white cast iron has been changed to free or temper carbon (or temper graphite) by suitable heat treatment. See the article in this Handbook on "Malleable Cast Iron."

Gray Cast Iron—Gray cast irons are cast irons which as cast have combined or cementitic carbon not in excess of an eutectoid percentage—the balance of the carbon occurring as graphite flakes. The term "gray iron" is derived from the characteristic gray fracture of this metal.

*Metallurgist, Deere & Co., Moline, Ill.

†Metallurgist, The Lunkenheimer Co., Cincinnati.

The great majority of castings designated as cast iron castings are gray iron castings. Excellent casting properties, ready machinability, and a wide range of strengths from which selection can be made together with other useful properties, promote good ultimate economy and explain the wide useage of this material where high dynamic stress resistance and high shock resistance are not governing factors in selection.

Gray cast irons are alloys of iron, carbon and silicon. Alloys (such as nickel, chromium, molybdenum) may be added to modify and sometimes to enhance desirable properties. Matrix structure usually is largely pearlitic. By suitable heat treatments, by alloy additions and by other means, various other matrix structures can be produced—ferrite, martensite, or austenite—as may be desired.

Semisteel—The term semisteel is now obsolete and is no guarantee of any specific and useful property in the metal.

Pearlitic Irons—Pearlitic iron is cast iron with a pearlitic matrix. So defined, any iron containing from 0.60-0.90% combined carbon is a pearlitic iron.

High Strength Iron—The term high strength iron has no definite meaning—in some circles it indicates metal over 40,000 psi. tensile strength, while some metallurgists regard only metal over 50,000 psi. tensile as high strength cast iron. In description and specification the specific class intended should be designated. (See Section IX, Classification of Gray Cast Irons.)

Austenitic Cast Irons—These are gray cast irons containing sufficient and suitable alloy content to lower the eutectoid transformation temperature below atmospheric temperatures. This results in retention of an austenitic matrix, with graphite flakes dispersed throughout. Nickel is the commonly used alloy for this purpose. Copper, chromium and molybdenum may be used to abet the action of nickel, or to modify the properties of both. Austenitic cast irons possess unusual magnetic and corrosion resistance properties. (See Section VII and XIII).

Graphitic Steels—An ultimate stable state in the iron carbon alloys (including both steels and cast irons) is reached when all the carbon occurs as graphite. That means by suitable choice of treatment and composition the carbide of any carbon alloy apparently can be graphitized. The fundamental definition of a cast iron is "an eutectiferous alloy of iron and carbon". In pure iron carbon alloys that region above 1.7% carbon is within the eutectiferous range. Various additions (notably of silicon) shift the eutectic concentration. For example, with 2.0% silicon the lower limit of the cast irons is somewhere around 1.1% carbon. Whether an alloy is a true graphitic steel or a special cast iron can be ascertained by application of the principle cited above. It may be noted that some of the lower carbon white irons (approaching the steel series) have appreciable malleability at temperatures well above the eutectoid and that cast irons and graphitic steels (when graphite is in nodular form) have definite ductility.

Alloy Cast Iron—The term alloy cast iron is used to designate irons to which alloying elements, such as nickel, chromium, and molybdenum have been purposely added.

II—Manufacture and Uses of Cast Iron

Gray Iron (Cupola Practice)—The major portion of the gray iron produced in this country is melted in the cupola furnace. The cupola is a vertical, cylindrical type of furnace consisting of a steel shell lined with fire brick (Fig. 1). The furnace is charged through a charging door which is located 15-20 ft. above the bottom plate. At the lower end of the furnace is the wind box, or air chamber, as shown in the diagram. Air enters the cupola through the tuyeres. The cupola is a simple and an economical melting unit because the fuel and the metal are in intimate contact with each other.

Fuel, metal, and flux are charged through the charging door of the cupola. Coke is charged first and the initial charge is known as the bed charge. Iron is then charged upon the coke. Alternate layers or charges of coke and iron are introduced into the cupola. Where flux is used it is charged on the coke. The coke bed is ignited by means of kindling wood or an oil torch. The bed charge or coke usually extends from 28-50 in. above the top of the tuyeres.

The charge of iron depends upon the capacity of the cupola. The cupola sizes are referred to as the inside diameter of the lining of the cupola. Cupolas may range in size from 18 in. dia. inside the lining to over 100 in. The size used for ordinary commercial practice varies from 42-84 in. in dia. The rated capacities on these sizes are from 5-25 tons of metal melted per hour.

The amount of metal charged into the cupola varies considerably, due to local conditions and opinion. Following are sizes of charges which are used in some foundries for various size cupolas:

48 in.....	1500 lb.
60 in.....	3000 lb.
72 in.....	3000 lb.

The size of charges may vary considerably from the figures given, but still be considered good practice.

The quantity of coke used depends upon the quantity of metal charged. The bed charge is a definite height above the tuyeres. Consequently, this portion of the coke goes in by volume instead of by weight. The succeeding charges of coke are in direct proportion to the metal charged. This proportion varies from one part of coke to 7-12 parts of iron.

The metal charged into the cupola consists of gray iron scrap and pig iron. Steel scrap is also used where strength of the finished casting is important. The proportions of gray iron scrap, pig iron, and steel scrap are governed by the type of castings. It is customary to find considerable difference in mixture of metal used, even among foundries making the same class of work.

Limestone is used as a flux in cupola operation. The purpose of the flux is to form a slag with the dirt, impurities in the metal, and the coke ash. Fluorspar (calcium fluoride) is sometimes used as a fluxing agent in combination with the limestone. The purpose of the fluorspar is to thin the slag and also to aid in the removal of sulphur, although correct proportions of limestone will insure a fluid slag and some sulphur removal. Various forms of soda ash are used as fluxes, particularly in the ladle. Intelligent slagging improves the quality of the iron.

The air is introduced into the cupola through the tuyeres. The volume of air introduced is important and governs the melting rate of the cupola. The air is used in the combustion of the coke, which in turn melts the iron. In most foundries about 30,000 cu.ft. of air are used to melt 1 ton of iron. If this figure is greatly exceeded there is a possibility of wild iron, due to excess air. Under ordinary conditions the blast pressure will vary from 8-20 oz., depending on the cupola height, number of charges, and character of charged stock. Some of the larger production foundries have increased blast pressure, in order to obtain greater capacity from the cupola, so that blast pressures in the neighborhood of 30 oz. are used.

Devices are available which permit control of the weight of air entering the cupola. This method is more accurate from the standpoint of control than is the measurement of the air volume.

The metal mixture entering the cupola is governed by the composition of the metal desired for the finished castings. Pig iron is the base of the charge. Charges are seldom made up entirely of scrap. Since the pig iron is of known composition, the greater the amount of pig iron and the smaller the amount of purchased scrap, the more uniform will be the composition of the resulting castings. For high grade castings such as automobile cylinders, the percentage of pig iron is about 35-45% of the charge, while for castings such as sash weights practically no pig iron will be used.

Summary of Cupola Furnace Data for Gray Iron—The following figures are given for normal operations of a cupola. Cupola practice varies considerably, and consequently the figures shown are only given as a guide. Wider limits beyond these figures may be used, and may still be consistent with good practice.

Area of melting zone of cupola in square inches multiplied by 0.75 gives a suitable weight in pounds for iron charge.

One pound of coke is required to melt 8 lb. of iron, figuring coke both in bed and between charges.

125 cu.ft. of air are needed to burn 1 lb. of ordinary coke to carbon dioxide.

Approximately 30,000 cu.ft. of air are required per ton of metal melted.

Melting 8 lb. of iron per sq.in. of cupola area per hour is considered a normal melting rate.

Tuyere area for a 36 in. cupola may be $\frac{1}{4}$ the cupola area and for an 84 in. cupola it may be $\frac{1}{10}$, with other sizes in proportion.

Electric Furnace Melting—During the past few years there has been a steady increase in the utilization of electric furnace melting for cast iron. This is particularly true in the production of special cast irons. The electric furnace lends itself to a high degree of control in respect to composition and temperature. In some cases, large quantities of scrap, such as borings, can be utilized and a good

grade of castings produced. The lower cost of scrap metals for the electric furnaces helps to compensate for the excess melting cost as compared to the cupola.

Two types of electric furnaces are in general use: (a) Three-phase direct arc, and (b) single phase indirect arc of the rocking type. Good results are reported from both types of furnaces.

In some cases the electric furnace is used for the entire melting process while in other cases a duplex method is used. In the duplex method all or part of the charge is melted in the cupola and the molten metal is refined and superheated in the electric furnace. Additions of alloys and steel may be made to the metal in the electric furnace. For steady production the duplex method is usually more economical, due to the low melting cost in the cupola.

Air Furnace Melting—The air furnace (see article on Malleable Cast Iron) is used to a limited extent in the production of gray iron castings. It is frequently used for the higher strength cast irons. The air furnace lends itself to accurate control of composition and higher pouring temperatures are obtained than with the cupola.

Horizontal rotary furnaces (cylindrical in shape) fired with pulverized coal or oil are used to a considerable extent in Europe. Two well known furnaces of this type are the Brackelsberg and Sesci. The furnaces lend themselves to a good degree of control of composition and temperature. The use of these furnaces in the United States was small until about five years ago. During the past five years a number of these furnaces have been installed for gray iron, special white iron, and white iron for malleable castings.

Uses—Gray iron castings are used for a large variety of articles varying in weight from a fraction of a pound to several hundred pounds. A few of these uses are automobile cylinders and pistons, locomotive cylinders, agricultural machinery, machine tool castings, stove castings, car wheels, dies, engine frames and beds, flywheels, water pipe, soil pipe, and hardware.

III—White and Chilled Irons—White cast irons contain practically all their carbon in the combined form, largely as free cementite (Fe_3C) and as pearlite or one of its transition forms. The presence of a large amount of cementite makes the material quite hard and brittle.

White cast iron, to be used as such, usually is produced by proper adjustment of composition. Low silicon content usually is required. Carbide stabilizing elements such as chromium may be added. For methods used in producing white irons in the malleable industry, see the article in this Handbook on "Malleable Cast Iron."

Completely white irons (plain carbon) have comparatively few engineering applications because of their usual brittleness. White iron surfaces on castings are desirable for combating certain types of abrasive wear. It is possible to produce castings with hard white iron exteriors and tough, strong gray iron cores. These castings, usually called chilled castings, may be produced in two ways: (a) By composition adjustment, and (b) by quick cooling by metal "chills." The first method is frequently employed when all the casting surface is required to be chilled. The second method is used to produce localized hardness.

In the first method the desired depth of chill may be obtained by the adjustment of silicon and carbon and other elements. With composition the same, the depth of chill depends largely on the cooling rate, hence larger sections will show less depth of chill than smaller ones.

In the second method the depth of chill depends not only on the composition and thickness of the casting, but also on the heat conductivity of the chills. This depends on the conductivity of the metal in the chill (usually cast iron), its initial temperature, and its thickness. It may be pointed out that irons chilled by chill blocks are of such composition that they would be gray in fracture if cast into sand molds with equivalent section sizes. The hardness of the chill surface and the strength of the gray core can be increased by proper alloy additions.

Among the more common chilled and white iron castings are plow shares, chilled rolls, chilled car wheels, balls, stamp shoes, dies, and wearing plates of various sorts.

IV—Physical Constants* and Mechanical Properties

Transformation Ranges—The values given for transformation ranges are those determined by means of thermal phenomena exhibited on slow cooling.

- (1) The initial solidification point varies with the composition, and is lowered by an increase in carbon and silicon content. It may be as low as about 2066° in an iron of eutectic composition, and as high as about 2500°F. in a white iron containing 2.00% carbon and 0.85% silicon.
- (2) The "Final" solidification, or eutectic solidification, occurs at 2066-2102°F., according to the composition of the metal.
- (3) Steadite formation occurs at about 1750-1800°F.
- (4) Transformation of austenite (nonmagnetic) to pearlite (magnetic) occurs at about 1325-1350°F. in most slowly cooled commercial irons.

Contraction and Expansion—Patternmaker's rules allow $\frac{1}{8}$ in. per ft. for linear contraction of gray iron, and $\frac{1}{4}$ in. per ft. for white iron ($\frac{1}{8}$ in. per ft. is about 1%). This often is found inaccurate in practice, and due allowance must be made for mass, composition, effects of shape, mold, and core. Generally speaking, contraction lessens with increase in mass and increases with increase (in gray irons) in tensile strength.

Three contraction phenomena are exhibited during the cooling of a cast iron from molten state to room temperature: (a) In the liquid, (b) during solidification, and (c) subsequent to solidification. This is shown by the charts by Ash and Saeger, Fig. 2 and 3. These investigators found total linear contractions (2102°F. to room temperature) of about 0.67% for a highly ferritic gray iron to about 1.10% for irons of approximately pearlitic matrix. Typical white irons showed about 2.0% total linear contraction over the same temperature range. In all cases a slight expansion was noted at 1958°F.

Volume shrinkage during solidification ranged from negative shrinkage in "soft" irons to 1.94% in an iron containing about 0.90% combined carbon. The white irons had 4.0-5.5% volume contraction in the same range.

Coefficient of Expansion—The coefficient of expansion of gray irons in the range 0-500°C. (32-932°F.) is about 13×10^{-6} per °C. The expansion is about 10.5×10^{-6} per °C. in the range 0-100°C. (32-212°F.). The expansion varies somewhat with the type of iron and is somewhat higher in the softer and higher carbon irons.

Fig. 2—Specific volume-temperature relation of a white cast iron (Ash and Saeger, Trans., A.F.A., 1932, p. 189).

Fig. 3—Volume changes occurring in a typical gray cast iron (Ash and Saeger, Trans., A.F.A., 1932, p. 194).

For the temperature range from 1070°C. (1958°F.) to room temperature, the coefficient of expansion varies from 0.0000092-0.0000169 per °C. At room temperature the commonly used figure of 0.000010 per °C. is sufficiently accurate for ordinary temperature changes.

Density—The density (g. per cc.) of gray irons at room temperature varies from about 6.95 for open grained high carbon gray irons to 7.35 for close grained low carbon irons. Moldenke gives 7.69 as the density of a white iron. The density of liquid cast irons just above the final solidification temperature is about 6.23. The values for density may be converted into the weight in lb. per cu. ft. by multiplying by the factor 62.428. A gray iron with density of 7.20 weighs about 450 lb. per cu.ft.

Fluidity—The fluidity or "running qualities" of cast iron can hardly be considered a physical constant, but it is so important from a foundry viewpoint that it is considered here. Generally speaking, the running qualities depend on (1) the degree of superheat and (2) the composition of the metal. Carbon and silicon promote the running qualities of the metal. Contrary to general belief Spencer and

*Strictly speaking, the properties listed herewith are not "constants," but may vary considerably according to the composition and treatment of the irons. It is emphasized that the term cast iron denotes a whole series of alloys.

Walding¹ found that higher phosphorus content did not increase the running qualities aside from its influence on lowering the freezing point. Saeger and Ash² found that various metals "run" better in dry sand molds than in green sand molds.

Thermal Conductivity—The thermal conductivity is approximately 0.11 cal. per sq. cm. per °C.

Electrical and Magnetic Properties—Where high permeability, permanent magnetism, or nonmagnetic properties are desired, the unique properties of cast iron may be used to good advantage. Various irons are needed depending on specific services required.

A thorough study of the electrical properties of cast iron has been made by H. J. Partridge (Carnegie Scholarship Memoirs, 1928). He states that the highest magnetic induction and permeability are obtained with cast iron which has been annealed.

Tensile Properties—The tensile strength of gray cast iron made under good foundry practice may range from about 20,000 psi. for soft highly machinable classes to over 60,000 psi. for the strongest, as cast. By use of special heat treatments, small sections have been produced with tensile strengths above 100,000 psi.

The tensile test is a reliable one for cast iron if reasonable care is taken to obtain proper alignment of the grips during the test (see also Section IX, "Classification of Gray Cast Irons").

Gray cast irons do not show a true "elastic limit" as do steels. Gray iron stress-strain diagrams are curved practically from inception. Because of this, it is not possible to establish definite moduli of elasticity. The effective modulus of elasticity at 25% of the ultimate strength will range from about 12,000,000 for some of the weaker irons to over 25,000,000 for some of the higher strength irons. It has been shown that cast iron at room temperature can sustain a static load of 80% of its tensile strength without perceptible creep.

When stressed, all gray irons exhibit some plastic deformation or set. It is possible to remove all set at a given load by a few stressings to that load. For a given material, set increases with load increments, but more rapidly than the load increments.

Transverse Tests (See also Section IX)—The transverse test is widely used for foundry control and specifications. In this test, the test bar is supported on knife edges and broken by a load applied midway between supports. The distance between supports is the "span." Deflection at the center is measured. Usually the ultimate load in pounds and the ultimate deflection in inches are reported. Since the load and deflection depend on the span and size of section, as well as the material, the sizes of test bars and span are specified. Sometimes the results are calculated to "Modulus of Rupture" and the following formulas are used:

$$\text{Round Bar} = \frac{2.546 \times LS}{D^3}$$

$$\text{Rectangular Bar} = \frac{3 LS}{2 BH^2}$$

where L is span
S is ultimate or breaking load
B is width of bar
H is height of bar
D is diameter of bar

There is no constant relationship between tensile strength and transverse modulus of rupture. The modulus of rupture is the higher of the two values and usually increases with increase in tensile strength, but not in the same ratio.

Shear Strength—The shear test is of value in "exploring" a casting; that is, taking test pieces from the casting itself. The ratio of shear strength to tensile strength varies, and the ratio is higher for the weaker irons. On a series of tests covering irons of various tensile strength, the ratio of shear to tensile varied from 1.64 for the weakest iron (15,000-20,000 psi. tensile) to 1.01 for the strongest iron (55,000-60,000 psi. tensile).

Compression Strength—Cast iron is much stronger in compression than in tension. On a series of tests covering many types of cast iron the compression strength ranged from 65,000-160,000 psi. The ratio of compression strength to tensile strength varied from about 4.5-1 for the weaker irons to 2.5-1 for the stronger irons.

²C. M. Saeger and E. J. Ash, Volume Changes of Cast Iron, Trans., A.F.A., 1932, v. 40, p. 171.

Hardness—The Brinell hardness test is a useful one for gray iron castings. The Rockwell test is also used, employing the B scale and the steel ball. In the "as cast" condition commercial (nonalloy) gray iron castings will range from 130-210 Brinell hardness. The alloy cast irons will run higher and heat treated irons may run over 600 Brinell hardness. Ordinary white irons will range from 321-534 Brinell while alloy white irons may run above 600.

Endurance Limit—The endurance limit, or fatigue strength, appears to vary linearly with the tensile strength. Values for the endurance limit of from 0.4-0.6 of the tensile strength are reported. The values for endurance limit are not greatly reduced for temperatures up to 800°F. Above 1250°F. the endurance limit is as high as the tensile strength under prolonged steady load.

Impact Resistance—Accurate information on impact or shock resistance was not available until recently. For comprehensive data on a large number of irons, see "Report on Impact Testing of Cast Iron," A.S.T.M., Preprint, 1933. In general the impact resistance increases with tensile strength, although this is not true in all cases. Cast irons of high phosphorus content are lower in impact resistance than lower phosphorus irons of equivalent tensile strength.

General Comments on Engineering Properties of Gray Iron—Gray iron combines low melting and molding cost with ease of casting into intricate shapes, rigidity, great compressive strength, and ready machinability.

Shrinkage defects often occur when a large section abruptly changes into a smaller section. When designing gray iron castings, uniform section sizes should be adhered to if possible.

A close grained iron, low in total carbon, is the strongest, toughest and best finishing type of material. The structure and strength of gray irons are controlled by composition and cooling rate. The composition can be controlled in making up the charge. The cooling rate depends on section, size, and to a lesser degree upon pouring temperatures. Hence, castings of nonuniform section are inclined toward diversity in physical properties, and in the same section there is often some difference between the outside and the center of the section. Proper composition will tend to minimize this latter variation.

V—Effects of Common Elements

Carbon—Most commercial cast iron castings contain from 2.50-3.50% total carbon. This carbon may exist as free carbon or graphite (Fig. 4), as combined carbon or cementite (as found in free massive cementite) (Fig. 5), and the cementite lamellae of pearlite (Fig. 6), or in solution (as in molten iron and in austenite).

Graphitic carbon is soft and nontenacious, and in gray iron is found as black flakes (Fig. 4).

Cementite (a carbide of iron, Fe_3C) is intensely hard and possesses little ductility. Under certain conditions it may be decomposed into its constituents, iron and carbon.

At ordinary room temperatures iron can hold only a few hundredths of a per cent carbon in solution. This solubility rather suddenly increases to about 0.85% at the A₁ transformation temperature (approximately 1350°F., depending on composition), and there is further solubility increase as the temperature is raised.

The structure of a given cast iron depends in a large degree on the amount, size, and distribution of the various forms of carbon. The amount depends upon the percentage in the charged metal and on the influence of the melting process. The size and distribution of the various forms depends on the temperatures, time and other factors involved in the melting process, the rate that the metal is cooled from the molten condition, and of course, on the composition. These factors are discussed in detail in various later sections.

Silicon—Because of its action on the carbon, silicon is a very important element in gray iron metallurgy. It promotes and assists the decomposition of the combined carbon (in pearlitic and massive cementite) to ferrite and graphite. In absence of silicon nearly all irons have a white (cementitic) fracture. In changing white iron to gray, silicon makes commercial production of gray iron practicable. For strong irons, just sufficient silicon should be used to insure decomposition of all massive cementite, but not enough to effect decomposition of the cementite in the pearlite. An excess decomposition of the pearlite to graphite and ferrite gives a weak, soft metal.

Silicon also reduces the position of the eutectic some 0.30% carbon for each

per cent of silicon. This means that higher silicon pig irons are often lower in carbon than lower silicon irons. It is easier to produce low carbon cupola metal with higher silicon ranges.

Manganese—Manganese in gray iron may assume two forms: Manganese carbide, which is associated with iron carbide in pearlite; and manganese sulphide, which occurs as small slate colored inclusions throughout the metal. In ordinary commercial ranges, manganese has little effect on the mechanical properties of gray iron. About 0.30% of manganese above the amount theoretically required for combination with sulphur (which is 55/32 times the sulphur percentage) is necessary for mitigating the effects of that element. In most American irons sulphur runs from 0.06-0.12%, hence the usual range of manganese of 0.50-0.80% is sufficient.

Sulphur—Sulphur occurs largely as manganese sulphide, and rarely as iron sulphide. Under proper operating conditions, sulphur does not seem to exert harmful effects on gray iron in amounts up to 0.16 or 0.18%, provided there are sufficient amounts of manganese present to prevent chill. In absence of sufficient manganese, sulphur has a marked stabilizing action on the cementite and promotes chill.

Phosphorus—The phosphorus range in most American irons is from 0.10-0.90%. The irons from northern ores usually run low in phosphorus, and the irons from southern ores generally are in the higher percentage range. The phosphorus content of many foreign irons is much higher than that of typical American irons. Practically all of the phosphorus is present in the component known as steadite, and its effects will be discussed in greater detail under that heading.

VI—Structure of Cast Irons

Structure of Gray Iron—Gray iron is essentially an iron, carbon, and silicon alloy. It may contain the following major structural components: Graphite, ferrite, and any of the products of the austenite-pearlite transformation. With high alloy content, austenite may be retained. With rather slow cooling and low alloy content, pearlite is found. The matrix of most commercial gray irons is largely pearlitic. Rapid cooling or the action of alloys or both may result in various transition products, such as sorbite, troostite, or martensite. "Free" or "massive" cementite is not found in gray irons. Steadite is found wherever phosphorus is present. Phosphorus is found in practically all commercial gray irons.

Pearlite and Ferrite—The carbon in gray iron occurs in two forms. The combined carbon forms pearlite as in steel. In gray iron one part of combined carbon by weight gives about 117 parts of pearlite by volume. As in steel, with low combined carbon the matrix is largely ferrite. However, in gray iron this ferrite has in it a large number of flakes of graphite, and a phosphorus-rich component known as steadite. With about 0.60-0.70% combined carbon (in low phosphorus irons), the matrix is nearly all pearlitic. As in steel, with other factors equal, the strength and hardness increase with increase in pearlite. Leaving transition forms out of consideration, the highest test irons are almost all pearlitic. The converse is not necessarily true.

Graphite—The metallic matrix of gray irons is filled with thousands of curved flakes of graphitic carbon. These flakes are soft and weak and are similar in crystalline make-up to natural graphite (plumbago). Graphite flakes give gray iron its typical dark gray fracture and are responsible for its lack of appreciable ductility and the ease with which it can be machined. By breaking up the matrix these flakes lessen the strength of the iron. In fact their influence is so pronounced that it often overshadows all other factors controlling strength. Graphite flakes exert these effects according to their size, distribution, and amount.

The flakes are much lighter than the matrix, hence they occupy more volume. Three per cent graphite by weight will account for somewhere around 12% by volume. This is one reason for the profound effect of graphite on the strength of gray iron.

Large flakes usually indicate grain growth and slow cooling from casting temperature. This condition usually reduces the amount of pearlite, because of the decomposition of pearlite into graphite and ferrite.

Summing up, increasing graphite lowers strength, promotes softness and allows heavier roughing cuts. Highly graphitic castings contract less on cooling from casting.

Steadite—Steadite, a structural component in cast iron containing phosphorus, is identified by certain white dendritic formations distributed throughout the metal. These formations sometimes form a loosely joined network. The distribution of

the formations indicates that they have concentrated in the last portion of the metal to solidify.

 Fig. 7—Phosphide eutectic in cast iron. $\times 1000$.
 All photographs reduced $\frac{1}{2}$ in reproduction.
 Photomicrographs by R. M. Allen, Trans., A.P.A., 1931.

Steadite consists of iron phosphide (Fe_3P) dissolved in iron, and of iron phosphide. In irons of low phosphorus content (under 0.50%) some of the phosphorus, in the form of steadite, is in solid solution. In higher percentages much of the steadite consists of a cellular eutectic (Fig. 7), containing 10.2% phosphorus and 89.8% iron. The melting point of this eutectic is about 1800°F .

Free Cementite—White and mottled irons which have considerably over 0.70% combined carbon contain free cementite, which causes the metal to be hard and brittle. Small amounts of free cementite are present in some gray irons.

Effects of Mass and Cooling Rate—It is well known that the more slowly a given gray iron casting cools from the time of pouring, the lower in strength and hardness it is likely to be. This is frequently referred to as effect of mass or effect of section size, whereas in truth it is more accurately termed effect of cooling rate.

The more slowly a given iron is cooled through the graphitization range, the more complete the graphitization will be. Furthermore, on slower cooling there is greater opportunity for grain growth, including grain size and degree of lamination of pearlite and grain or flake size of graphitic carbon. These effects on the structure are reflected in the physical properties (Fig. 8) showing loss of strength with increase of section size.

Changes in strength and structure with variation in section size are much less apparent in irons of comparatively low total carbon content. For example, a 2.75% carbon, 2.25 silicon iron with no alloys, when properly made, can be cast into a 0.5 in. dia. test bar with no trace of chill and into a 3.0 in. dia. bar with pearlitic matrix having good strength and hardness maintained throughout. Quite frequently the intelligent use of alloys also is beneficial in maintenance of uniformity in strength and hardness over a range of section sizes.

General relationships of strength, structure, hardness, and section size are shown in Fig. 9.

VII—Alloy Cast Irons and Typical Analyses of Alloy and Plain Iron Castings

The term "alloy cast iron" is rather a loose term. All cast irons are alloys. The term "alloy cast iron" is used for those cast irons containing such elements as nickel, chromium, and molybdenum, and which are added because of their effects on the physical properties.

Alloy cast irons are frequently used for more severe service than are ordinary cast irons. In the manufacture of alloy steels, particular care is taken in the melting practice. Similarly in cast iron, the alloys should only be added to good irons to make them better, not to attempt to make a poor cast iron into a good one.

Nickel Cast Iron—Nickel is usually added to gray cast iron in amounts from 0.25-5.0% for general engineering applications. It is often added in combination with other alloying elements, such as chromium or molybdenum. Nickel additions influence machinability, texture, hardness, density, heat, and corrosion resisting properties, and resistance to wear. Nickel, like other alloying elements, must be used with care and discretion if economic benefit is to be derived from it. There is no universal formula for nickel cast iron, but each problem requires its own special prescription.

Nickel acts as a graphitizer and does not form a carbide. It is generally without marked effect on the graphite structure or grain of gray iron. In small amounts,

it will reduce chill and soften partially chilled iron by eliminating hard free carbide, thus promoting machinability. Larger amounts (over 5%) harden iron by forming sorbite and even martensite (Fig. 10). Martensitic irons offer unusual properties in wear resistance and find application in such parts as gears, dies, cylinder blocks, and brake drums.

The value of nickel in gray iron is primarily related to its effect on machinability. The use of nickel permits the production of castings which may be either harder, stronger, and of better structure with equal machinability in comparison with plain iron castings. or more readily machinable for the same hardness, strength, and structure.

Fig. 9—Qualitative diagram for cast iron showing section, tensile strength, and hardness relations.

production of castings which may be either harder, stronger, and of better structure with equal machinability in comparison with plain iron castings. or more readily machinable for the same hardness, strength, and structure.

Nickel promotes density and freedom from porosity by permitting the use of low silicon without chill or hard spots appearing in light sections. Up to about 4%, nickel in iron of suitable base composition promotes uniformity of grain, hardness, and strength throughout sections of considerable or uneven thickness.

The important relations between silicon content, structure, and machinability are recognized by the foundryman. The machinability may be indicated by the step bar test casting as shown in Fig. 11. The different steps of this test bar are fractured and examined and the hardness and combined carbon determined on the different sections. The effect of decreasing silicon content on chill is also shown in Fig. 11. In Fig. 12 is shown the effect of nickel in reducing chill. As the nickel is increased the hardness and strength of the heavier sections increase slightly, whereas at the same time the lighter sections become progressively more gray and more machinable.

As the amount of nickel is increased to from 10-18% there is a gradual change in structure to nonmagnetic gamma iron (austenitic) with corresponding important changes in properties.

Irons of varying coefficient of expansion can be produced. Up to 5% nickel, the expansivity is slightly lower than that of plain cast iron. At about 20% nickel, the expansion is 50% greater than plain cast iron; between 20 and 36% the expansivity decreases. At 28-29% nickel, the expansion is the same as plain iron. Above 36% the expansivity increases gradually so that at 45-50% the rate again parallels that of plain iron.

Austenitic gray irons (Ni 14%, Cu 5.5, Cr 2-6, Si 2 and total C 3%) are practically free from growth and are nonscaling at temperatures up to 1500°F. They are superior to ordinary gray irons in resisting the action of many acids, alkalis, salts, and other corrosive agents.

The economic application of nickel to the production of specific castings requires a study of the individual problems. In Table I are shown some typical analyses of gray iron castings, including nickel iron castings. These are examples only and no attempt has been made to cover the entire field of alloy and nonalloy cast irons.

Chromium Cast Iron—Chromium is essentially a carbide former in contrast to the graphite forming elements such as silicon and nickel. Chromium in sufficient amount increases the combined carbon and intensifies the chilling propensities of gray iron. Chromium iron double carbides are more stable than straight iron carbides and graphitize less readily.

One of the important uses of chromium is the addition of this alloying element to base irons where additional hardness or wear resistance is required. For example, the base iron in a foundry may have a silicon content of 2.25% and 3.40% total carbon. This iron is suitable for the bulk of the castings produced, but not for some of the heavier castings and for some medium section castings where a maximum of wear resistance is required. Additions of chromium, ranging from 0.40-1.00%, frequently are of considerable value. In heavy sections, the use of chromium helps to give a more uniform structure and tends to eliminate porosity.

Fig. 10—The effect of nickel on the Brinell hardness of gray iron (arbitration bars).

The approximate effect of chromium on a soft iron is as follows:

Chromium, %	Structure
0	Ferrite and coarse graphite
0.30	Less ferrite and finer graphite and pearlite
0.60	Fine graphite and pearlite
1.0	Fine graphite and pearlite and small carbides
3.0	Graphite disappears
5.0	Much massive cementite
10.0-30.0	Fine cementite

Chromium additions reduce the graphite carbon content, decrease the flake size, and favor the formation of more finely laminated and harder pearlite. For suitable base irons, these effects add to tensile strength, promote finer grain size, and increase hardness. The effects of chromium additions on the Brinell hardness and combined carbon content of gray iron is shown in Fig. 14. Above a certain maximum, usually about 1% chromium in soft irons of medium section, free carbides appear with resulting difficulty in machining. Unless graphitizing alloys such as nickel are added, 3% chromium irons usually have an entirely white fracture. Higher percentages of chromium may be added to produce special purpose white irons, where freedom from scaling toughness or chill are desired. Considerable work is being done on cast irons with chromium contents from 15-35%, and very excellent results have been secured in improving heat and corrosion resistance. For applications up to about 1300°F. (for service comparable to ordinary grate bars) the use of about 1½% chromium has been valuable in eliminating growth.

Chromium increases the tensile strength at elevated temperatures and minimizes tendency to growth in cast iron.

The carbide stability conferred by chromium is useful in gray iron heat treatment because the iron does not offset by excessive graphitization the advantages conferred by structural changes in the matrix.

Nickel-Chromium Cast Iron—Nickel-chromium gray cast irons are currently produced in a variety of compositions, suited to the particular casting or foundry problems for which they were designed. The range is generally not over 3.0% nickel and 1.0% chromium. Nickel and chromium are used together in gray iron primarily for the purpose of refining its structure and of hardening and strengthening it without impairing its machinability.

The addition of about 4.5% nickel and 1.5% chromium to a chilled or white cast iron is being used to give an extremely hard, tough, and strong product. The hardness of such a material will range from 600-750 Brinell as against 380-530 for corresponding grades of plain chilled or white iron. The strength is approximately doubled and the toughness significantly increased.

Nickel and chromium are added to gray iron in the proportion to which they mutually neutralize each other in respect to chill. The resulting alloy iron will have the same chilling tendency as the plain iron to which the alloys were added, and castings made from it will be as readily machinable as

Fig. 11

Fig. 12

Fig. 13

castings made from the plain base iron. At the same time the refining, matrix hardening, and strengthening effects of both alloys will be conserved and reflected in

the structure and properties of the casting. Fig. 13 and 15 illustrate the effects of adding nickel and chromium to gray iron.

The usual ratio of nickel to chromium for additions to gray iron is 2½-1. This ratio usually gives good results in respect to machinability and physical properties. Other ratios have been used with good results, the relative amounts of nickel and chromium depending on the base iron and the application.

Nickel-chromium cast irons are used for castings where better structure, greater hardness, wear resistance or strength are required in machinable irons. The use of nickel and chromium is frequently more convenient than adding nickel alone, because it creates less disturbance in the foundry to add nickel and chromium to the regular base iron than to change the cupola mix (in order to lower silicon content) and use nickel alone. Nickel and chromium are frequently cheaper than additions of nickel alone. The usual amounts of nickel and chromium added to gray iron to harden and strengthen it vary within the following limits:

	Nickel, %	Chromium, %
Small addition	0.10-0.50	0.10-0.25
Medium addition	0.75-1.50	0.25-0.50
Maximum addition	2.00-3.00	0.57-1.00

Typical examples of some nickel-chromium cast irons are shown in Table I.

Molybdenum Cast Iron—Molybdenum in cast iron forms both complex carbides and solid ferrite solution. As a carbide former it is much less drastic in its action than chromium. It may have a beneficial effect on the shape of the graphite flakes, causing them to be somewhat nodular in form, with consequent improvement in physical properties.

The addition of molybdenum to a suitable gray cast iron increases tensile strength, transverse strength and deflection, and hardness. Molybdenum is usually added in quantities from 0.25-1.25%. It is the most effective alloying element added to gray cast iron to increase strength. Up to about 1.5% it increases tensile and transverse strengths. Above 2% there is a dropping off in strength (Fig. 16 and 17).

Molybdenum is also used in combination with other alloying elements. For high strength irons, nickel and molybdenum are frequently used in combination. Molybdenum and chromium are also used. Another popular combination is molybdenum, nickel, and chromium.

A number of investigators report that molybdenum increases the wear resistance of cast iron (Fig. 18).

The addition of molybdenum to cast iron promotes structural uniformity in heavy sections. As a result, good density, high Brinell hardness, and high strength are maintained throughout the cross section.

Molybdenum retards the critical transformations in both the liquid and solid state. This makes the volume changes less drastic and the rate of graphitization slower. Such effects help in heat treating processes, also in the retention of strength and other properties at elevated temperatures.

When properly used, suitable machinability is obtained with molybdenum cast iron.

Vanadium Cast Iron—

Vanadium is added to cast iron in amounts varying from about 0.10 to about 0.50%. The following effects are observed:

- (1) Interference with graphitization; that is, stabilization of cementite.
- (2) Smaller graphite flakes and more uniform graphite distribution.
- (3) A tendency to promote sorbitic structure.
- (4) Decreased grain size of matrix.

Fig. 14—Effect of chromium on the hardness and combined carbon of gray iron (arbitration bars) (Trantin).

Fig. 15—The Effect of Ni and Cr in different proportions on the combined carbon content of gray iron (Piwowarsky).

Fig. 15—The Effect of Ni and Cr in different proportions on the combined carbon content of gray iron (Piwowarsky).

(5) Smaller, less pronounced, and less perfectly aligned dendrites in the surface layers of chilled castings. Due to this and (1) above, greater depth, hardness, toughness, and wear resistance of chill result.

(6) Resistance of the carbide to decomposition at elevated temperatures.

These results of vanadium additions are largely a carbide-stabilizing effect. Vanadium is the most powerful of the carbide forming elements. It lowers the eutectoid ratio more rapidly than any other element and gives evidence of forming carbides which are stable at moderately elevated temperature.

Recent work on vanadium cast irons indicate that vanadium additions increase tensile strength, transverse strength, and hardness of gray cast iron. For many commercial applications the vanadium content ranges from 0.10-0.25%. Vanadium is also used in combination with other alloying elements such as nickel, chromium, and molybdenum.

Titanium Cast Iron—Titanium has a graphitizing influence on cast iron similar to silicon but stronger than that element in small amounts. Its addition causes an increase in ferrite formation and a decrease in the chilling tendency. Titanium has a refining action on the size of the graphite particles and this results in increased strength. The deoxidizing and scavenging effects of titanium on cast iron have been reported. Titanium has been used in combination with chromium with favorable results in regard to strength and machinability and good results have been reported from the use of titanium with molybdenum and vanadium.

Table I
Typical Analyses of Some Commercial Gray Iron Castings

Casting	Per Cent							
	Total C	Si	Mn	P	S	Ni	Cr	Mo
Auto cylinder, plain iron.....	3.25	2.25	0.65	0.15	0.10

Valves and fittings (medium).....	3.30	2.00	0.50	0.35	0.10

Aluminum Cast Iron—Between 1.0 and 1.75% aluminum is effective in producing extreme hardness in the nitrided case of cast iron. A disadvantage is the fact that when aluminum cast iron is poured, a tenacious oxide skin forms on the surface, getting thicker as the pouring proceeds, and finally creating unsound places in the casting.

Zirconium Cast Iron—In an iron of suitable composition, with low silicon, zir-

contum additions improve physical properties. In amounts from 0.10-0.30% zirconium deoxidizes cast iron and raises strength and resistance to impact.

Copper Cast Iron—During the past few years there has been a large increase in the use of copper in cast iron. The range is from 0.25-2.5% for engineering applications. In a number of commercial applications combinations of copper and chromium have been used, also copper and nickel.

Vanadium cast iron is used for a number of purposes, the following analyses being typical:

Casting	Per Cent							
	Total C	Si	Mn	S	P	V	Cr	Ni
Grate bars	3.68	1.72	0.53	0.09	0.43	0.14
Locomotive cylinders	3.47	1.54	0.53	0.10	0.49	0.13
Forming dies	3.40	1.30	0.50	0.08	0.23	0.12
Steel mill rolls	3.50	1.10	1.20	0.10	0.20	0.35	1.85	4.00
Bottle molds	3.30	1.65	0.60	0.07	0.30	0.14

VIII—High Strength Cast Irons—The term "High Strength Cast Iron" is usually employed to indicate cast irons ranging above 40,000 psi. in tensile strength. As this term is rather vague, a more desirable method of designating cast iron is to use the A.S.T.M. classifications shown in Section IX (see also definition in Section I).

Rapid progress in the manufacture of high strength irons has been made in the past five years. Irons of 35,000 psi. tensile strength were considered high strength only a few years ago, while today many foundries are regularly producing irons above 50,000 lb. in tensile strength. Strengths in the neighborhood of 70,000 psi. may be obtained in the "as cast" condition.

It should be remembered that the higher strength irons are more difficult to produce and their cost is higher. Also the machinability is usually decreased with increased strength. Consequently these irons should not be specified except where extra cost is justified.

Fig. 16—Effect of molybdenum on the properties of gray cast iron (Smith and Aufderhaar).

Fig. 17—Effect of molybdenum on strength properties of cast irons (Musatti and Calbani).

Fig. 18—Amsler wear tests of cast iron (Musatti and Calbani).

Another cupola iron having about the same strength had almost the identical composition except that 0.35% molybdenum had been substituted for the nickel.

Air furnace irons with minimum tensile strengths of 50,000 psi. may have the

The size, shape, distribution, and quantity of the graphite in cast iron have a large influence on the strength of the iron, usually higher strength irons are low in total carbon content. This is particularly true in irons having tensile strengths above 50,000 psi., the total carbon usually being 3% or under.

In the cupola process a considerable quantity of steel is often used in the charge. Also, alloys may be used for machinability and strength. Therefore, alloying elements such as nickel, nickel-chromium, and molybdenum are frequently used in high strength irons.

Following is the composition of a cupola iron having a tensile strength of about 70,000 psi.: Total C 2.60%, Si 2.15%, S 0.08%, P 0.08%, Mn 0.70%, and Ni 1.10%.

following range of composition: Total C 2.75-3.00%, Si 1.80-2.20%, Mn 0.40-0.60%, S 0.05-0.08%, and P 0.14-0.18%. While this range of composition shows no alloying elements, such as nickel, many air furnace irons have substantial alloy contents.

Electric furnace high strength irons may be made with or without alloys; the following iron had a tensile strength of about 55,000 lb. and a Brinell hardness of 241 on the standard 1.20 in. dia. test bar:

Total C 3.02%, Si 2.35%, S 0.09%, P 0.13%, Mn 0.80%, N 0.44% Cr 0.37%, and Mo 0.58%.

These various examples have been given to show that high strength irons may be made in a number of ways. We are not restricted to any one melting method or one type of composition. However, the high strength irons require closer metallurgical control than do the common grades of cast iron.

High strength gray irons can also be produced by heat treatment of white and gray irons. This is discussed in Section XIV on Heat Treatment.

Meehanite—Meehanite is the trade name applied to cast irons in which the molten metal has been treated with calcium silicide. The metal may be melted in the air furnace, cupola, or electric furnace, and a large portion of scrap metal is usually employed. The composition is adjusted so as to produce a metal which would be a white iron in case the calcium silicide were not added. Calcium silicide is then added and it acts as a graphitizer and also gives a fine graphite structure. Some high strength irons are produced in this manner.

IX—Classification of Gray Cast Irons—There are many classifications which might be set up to cover the alloys of iron, carbon, and silicon known as cast irons. The most important classification of gray irons from an engineering viewpoint is that employed in the A.S.T.M. specification, A48-36.

In these specifications gray iron castings are classed according to minimum tensile strengths of test bars, as follows:

Class, No.	Tensile Strength, Min., psi.
20	20,000
25	25,000
30	30,000
35	35,000
40	40,000
50	50,000
60	60,000

Transverse tests are optional, and the following minimum breaking loads are specified:

Transverse test bar.....	0.875 in., Dia. 12 in. Supports	1.2 in., Dia. 18 in. Supports	2.0 in., Dia. 24 in. Supports
Span length	Breaking Load at Center, Min., lb.	Breaking Load at Center, Min., lb.	Breaking Load at Center, Min., lb.
Class, No.			
20	900	1,800	6,000
25	1,025	2,000	6,800
30	1,150	2,200	7,600
35	1,275	2,400	8,300
40	1,400	2,600	9,100
50	1,675	3,000	10,300
60	1,925	3,400

By agreement between manufacturer and purchaser, deflection values in the transverse test may be specified.

Three sizes of test bars are specified in order to represent various thicknesses of castings by simulating various cooling rates. If the manufacturer and purchaser agree on the controlling section of the casting, the corresponding test bar used is as follows:

Controlling Section of Casting, in.	Test Bar	Nominal Diameter of Test Bar as Cast, in.
0.75	A	0.875
0.75-1.25	B	1.20
1.25-2.00	C	2.00

For sections of castings over 2.00 in., test bar C may be used or a larger test bar may be chosen by agreement between the manufacturer and the purchaser.

The transverse test bars used have the following dimensions:

Test Bar	Dia., in.	Length, in.	Distance Between Supports in Transverse Test, in.
A	0.875	15	12
B	1.20	21	18
C	2.00	27	24

It is recognized that there is no definite factor for correlation between tensile and transverse strengths for various types of cast iron. Tables included in the specification give minimum values only.

It is the intent of these specifications to subordinate chemical composition to physical properties. By agreement between the manufacturer and purchaser, the quantities of any chemical elements in cast iron may be specified.

Other A.S.T.M. Specifications—The A.S.T.M. has developed other specifications for various types of gray iron castings, as follows:

A.S.T.M. Designation	Title of Specification	A.S.T.M. Reference
A44-04	Specification for Cast Iron Pipe and Special Castings	1936 Book of Standards
A45-14	Specification for Cast Iron Locomotive Cylinders	1936 Book of Standards
A46-30T	Tentative Specification for Chilled Tread Cast Wheels	1936 Book of Tent. Standards
A126-30	Specification for Gray Iron Castings for Valves, Flanges and Pipe Fittings	1936 Book of Standards
A142-32T	Tentative Specification for Cast Iron Culvert Pipe	1936 Book of Tent. Standards
A159-35T	Tentative Specification for Automotive Gray Iron Castings	1936 Book of Tent. Standards

Other possible bases for the classification are by composition, by hardness, and by structural features. From an engineering viewpoint there are many definite reasons for the classification employed in the A.S.T.M. Specification A48-36. Other classifications may serve useful purposes, and advances in the technology of cast irons undoubtedly will encourage development of such classifications.

X-Wear—Like the term hardness, the term wear has generic rather than specific significance. In a general way, wear signifies a gradual eating away or dissolution of a structure resulting from the action of mechanically applied agents. Often mechanical wear and deterioration by corrosion act concurrently. The wearing agent may be a fluid (gas or liquid) or a solid. Such agents break off or tear off small particles of the metal, whereas in case of corrosion chemical action results in formation of new compounds, distinct from the original metal.

With a perfect lubricant film there can be no wear. Wear occurs when there is no lubricant, or when the lubricant film breaks down, or when the lubricant is imperfect and a carrier of wearing agents.

In the case of metal to metal wear (no lubricant) gray cast iron reveals a high degree of usefulness. Its highly heterogeneous structure rather effectively inhibits seizure and galling. It not only wears well on itself, but also with many other alloys. It has a tendency to cut much softer alloys, but usually works well with alloys as hard or harder than itself. This property of gray iron is among those responsible for its extensive use in machine tools, where heavy pressures and imperfect lubrication occur, and in automobile cylinders, where temperature and partial lubricant breakdown are factors. An example of metal to metal wear is in automobile break drums. With hardness and lubrication equal, gray iron, with its graphitic structure, is far more free from tendency toward seizure than any of the nongraphitic ferrous alloys.

The properties in gray cast iron which are associated with low rate of wear are pearlitic matrix, high hardness, and high strength. Other things being equal, an iron with a pearlitic matrix will resist wear better than one containing free ferrite.

To compare dissimilar irons, hardness does not always have a direct relationship to wear. However, for the same type of cast iron, higher hardness frequently results in a much lower rate of wear.

Heat treatment or special alloy additions which produce martensite, sorbite, and like hard matrices somewhat improve wear resistance. Usually some increase in resistance to metal to metal wear may be expected from such increased hardness. However, the major gain is from increase resistance to abrasive action (sand or grit). Localized heat treatment (flame hardening) has proved useful.

White cast irons are in general relatively resistant to abrasion. Some of the recent hard white irons not only are resistant to abrasive influences but also have a high degree of resistance to galling and seizure.

Because there are many types of wear it is practically impossible to set up any laboratory test which will give an adequate measure of the wear resistance of a material in service. However, laboratory tests have been of value in helping to develop better materials for resisting wear. Some of the conclusions from laboratory tests are as follows:

- (1) Wear resistance increases with matrix hardness.
- (2) With increasing combined carbon content, the resistance to wear of gray irons increases rapidly up to 0.60% combined carbon and then slightly up to 0.85%.
- (3) Permanent mold cast iron wears away faster than sand cast iron of the same combined carbon content.
- (4) Increasing silicon content decreases resistance to wear.

XI—Machinability—For most gray iron castings machinability is a most important property, yet it is not readily measurable. One shop may consider an iron machinable while the next shop will find it unsatisfactory. Machinability ranges are wide and cast irons may be made to suit many conditions, remembering that ease in machining is usually inversely proportional to the strength of the casting.

Machinability of metals has been variously determined with reference to: (1) Tool life, (2) type of finish obtained, and (3) power required. The difference in machinability with reference to tool life is of the greatest practical importance.

The composition, structure, and physical properties of cast iron extend over a wide range. Dependent upon these factors, cast iron varies from one of the most readily machinable to the most unmachinable of ferrous materials. At one extreme of this range we have completely annealed permanent mold cast iron, which is the most readily machinable; at the other extreme is white or chilled cast iron. Annealed permanent mold cast iron possesses excellent machinability because the structure consists of iron containing no combined carbon, and broken up by a high percentage of finely divided free carbon flakes, together with freedom from burned-in sand at the surface. Chilled or white iron is extremely difficult to machine because its structure is composed chiefly of hard iron carbide in both pearlitic and massive form, unbroken by any flakes of free carbon. The machinability of a cast iron may be said to depend upon the proportions and arrangement of the hard and soft microstructural components. Cast irons may be classified according to their microstructure (and in order of ease of machinability) as follows:

- (1) Ferritic (free carbon and silico-ferrite).
- (2) Pearlitic-ferritic (free carbon, silico-ferrite, and pearlite).
- (3) Pearlitic (free carbon and pearlite).
- (4) Mottled iron (pearlite, free carbon, and enough massive cementite to produce a mottled fracture).
- (5) White iron (pearlite and massive cementite).

Additions of alloys such as nickel, chromium, and molybdenum have an effect on machining. When nickel is used with lower silicon content or with lower silicon and chromium it permits machining irons of considerably higher hardness than could be machined without the use of nickel. The reason for the ability to machine irons of 225-250 Brinell in alloy compositions is that no massive carbides exist in the matrix. As soon as the plain cast iron exceeds a hardness of 200-220 Brinell it usually contains hard carbides, especially at the edges and corners of light castings.

Chromium is a carbide former, and if as much as 0.25% is added to a plain

Fig. 19—Tensile strength of various irons at elevated temperatures (J. W. Bolton, Trans., A.F.A., 1930, p. 505).

Fig. 20—Tensile strength after heating 500 hr. Tested at elevated (annealing) temperatures.

cast iron which is already at the limit of machinability, the iron may become unmachinable. Care should therefore be taken in adding chromium, where machinability is a factor. However, on many soft irons, as much as 0.50% chromium may be added with little effect on machinability.

Also the high chromium irons (35% chromium), although white irons structurally, are softer and more readily machinable than ordinary white irons.

Molybdenum is frequently used as an alloy addition in cast iron to obtain increased strength and wear resistance. Where molybdenum is used to increase hardness and strength without the formation of carbides, machinability will usually be inversely proportional to the hardness and strength produced.

The graphitic steels, because the chip is easily broken due to presence of graphite, machine much more readily than ordinary steels of similar combined carbon content and hardness.

The surface condition of iron castings is most important in determining machinability. Frequently castings are condemned as unmachinable when the metal itself is quite machinable, but difficulty is caused by the presence of burned-in sand on the casting. Where burned-in sand is present any attempt to make light surface cuts will cause rapid failure of the tool. A sufficient depth of cut must be made to insure the point of the tool being well below the surface of the casting.

The character of the surface finish obtained in machining cast iron under light cutting conditions is principally dependent upon the size of the graphite flakes and the total amount of the graphite. A high total carbon, high silicon cast iron with large graphite flakes will show a pitted surface when machined due to tearing out of particles of metal in between the graphite flakes. Rough cuts taken on coarse grained cast iron will exaggerate the pitted appearance by tearing out small particles of iron. The lower carbon irons will give a much better appearance on machining.

XII—Effects of Temperature on Cast Iron—The effects of temperature on cast irons may be manifested in two ways: (1) Effects on mechanical properties, and (2) deterioration of the material due to certain structural and chemical changes which may occur at elevated temperatures. These factors are in some cases interrelated.

Boiler codes based upon the A.S.M.E. recommendations do not permit the use of cast iron for pressure containing structures beyond 450°F. and 250 lb. pressure for steam service. This regulation is based upon certain findings by the A.S.M.E. in 1909, and the regulation may be unduly restrictive toward many of our modern cast irons. A proposed code (California—for unfired pressure vessels) permits the use of suitable classes of iron for temperatures up to 650°F.

In other applications requiring considerable mechanical strengths cast irons

frequently are used successfully at temperatures up to about 850°F. Beyond 850°F. practically all ordinary cast irons exhibit enough deterioration to render their utility for severe mechanical duty questionable.

It is possible to discuss the effects of temperature on cast iron only briefly in this section. Those further interested in this subject are referred to the A.S.T.M.-A.S.M.E. Symposium on the Effects of Temperature on Metals, 1931, p. 436-465, and the A.S.T.M.-A.F.A. Symposium

Fig. 23—Effect of quenching and tempering cast iron.

on Cast Iron, 1933, from which much of the material herein has been taken.

When judged by short time tensile tests, cast irons show very slight changes in their original tensility at temperatures up to 800°F. This is shown in Fig. 19 and

20. Kanter gives the following data on some samples of cast iron subjected to exposure for 70 weeks at 600 and 900°F., respectively.

	Original	After 600°F.	After 900°F.
Gray iron	25,300	24,600	18,100
Gray iron	34,400	30,600	23,600

That cast irons have marked resistance to "creep" at 600°F., but that this is somewhat lower at 800°F. is shown by the "creep" curves in Fig. 21 and 22. The curves marked "High Test" and "Nickel" Irons in Fig. 21 were stressed to 10,000 psi. as was the iron stressed at 10,000 psi. at 600°F. shown in Fig. 22. All three irons referred to were in the 40,000 psi. gray iron tensile class. The material marked "Gray Iron" was in the 30,000 psi. tensile class, and was therefore stressed higher in proportion to its tensile strength than the other materials.

Endurance or "fatigue" limit is lowered little up to 800°F., and the Brinell hardness is unchanged. There apparently is an appreciable lowering in compressive strength within this range. The wear resistance of gray irons is one of their unique characteristics, and evidently is maintained at moderately elevated temperatures. The satisfactory wear resistance of gray cast irons is shown by their successful applications in automotive, Diesel, and steam engine cylinders and pistons.

Because of low ductility and comparatively low impact resistance, cast iron should not be employed to resist high dynamic stresses in elevated temperature applications where failure would result in hazards to life or equipment.

Heat Resistant Cast Irons—Heat resistance of cast irons becomes an important factor when these irons are used at temperatures above 800°F. in air, and sometimes at even lower temperatures when used in superheated steam. Heat resistance depends in a large degree on resistance to growth and to certain corrosive influences, chiefly oxidation, which may result in serious scaling.

Growth in cast irons is due both to graphitization and to infiltration of corrosive gases. When ordinary gray iron is repeatedly heated to temperatures above 800°F. (depending on the type of iron) it usually shows a permanent increase in size, or growth as it is called. In most cases in a given iron, the amount of growth is proportional to the maximum temperature reached, and to the number of heatings. In some cases castings have been known to increase 50% in volume. Castings exhibiting growth are weak, misshapen, and brittle.

Irons most resistant to growth are found to have stable carbides and close dense grain structure. Therefore factors which stabilize carbides and produce close grain structure retard growth.

In regular engineering irons, those in the higher tensile classes with lower total carbon usually are more growth resistant and may be satisfactory in this respect up to about 850°F. for long periods. Low silicon usually is desirable and small percentages of chromium frequently prove advantageous. Under some conditions high phosphorus content retards growth somewhat, but due to various drawbacks, high phosphorus irons have not found wide favor for this purpose.

It is obvious that white irons, whose carbon is entirely in the combined form, are more growth resistant than gray irons which contain graphite flakes. Some white irons are limited in application because of their extreme hardness, brittleness, and low strength.

Special irons have been developed which possess extraordinary growth resistance. Perhaps the most widely used of these special irons are the austenitic cast irons containing 14% or more nickel, about 5% copper, and 1-4% chromium. Being austenitic, these irons do not expand and contract in passing through the range 1325-1350°F., where the pearlitic transformation in regular gray irons occurs. They resist oxidation well, even up to 1500°F. These austenitic irons when properly made are more ductile than regular gray irons.

The British have developed a special 6-8% silicon cast iron for which excellent heat resisting properties are claimed. The resistance of this material to deterioration depends on: (1) A completely ferritic matrix (there being therefore no carbide to decompose), (2) raising the transformation temperature above the working range, (3) fine grained graphitic structure, and (4) a dense matrix. The effectiveness of very high silicon content is shown by the following examples showing growth after 10 heatings up to 1832°F.

Carbon, %	Silicon, %	Growth, %
2.1	3.7	0.923
2.5	6.1	-0.011

The high silicon material, known as Silal, must not be confused with so-called high silicon gray irons, which rarely contain over 3.0% silicon. In true gray irons silicon promotes growth, as mentioned previously.

The 6-8% silicon irons are more brittle than gray irons. The 14% silicon irons are growth and scale resistant, but they are brittle.

The advent of the stainless steels has emphasized the high oxidation resistance conferred by high percentages of chromium. The carbide stabilizing tendencies of chromium have been mentioned in an earlier paragraph. It is therefore not surprising that high chromium cast irons (15-35% chromium) have been found both growth and scale resistant. It is claimed that in spite of a white iron structure certain of these alloys can be made machinable, and they have been advocated for applications up to 1800°F.

Certain irons with only modest percentages of chromium (0.30-1.00%) have been found much more growth resistant than gray irons, and possibly somewhat more scale resistant.

XIII—Corrosion of Cast Irons—Gray iron is employed widely in machinery and in equipment of many kinds, and its corrosion resistance is a subject of wide interest.

Use of cast iron water pipe dates back many years. The famous fountains at Versailles were installed about 100 years before the Declaration of Independence and part of the original cast iron piping system is still in use. Today cast iron remains the most widely used material for water main and soil pipe. Under most conditions its corrosion resistance is much greater than that of steel, and its cost lower.

Where stray currents do not cause electrolysis and where soils are not unusually corrosive cast iron pipe usually gives good service for almost indefinite periods. H. O. Forrest⁴ concludes, "It is evident that the rates of corrosion of the usual types of cast iron made in this country do not vary sufficiently to cause any great difference in length of life."

Although gray irons of different grades do not vary much in their degree of corrosion with a given water, different waters vary quite widely in their attack on gray iron. Problems encountered in handling corrosive fluids and solutions are legion. The nature of the fluid, its concentration, temperature and pressure, and the presence of impurities all have an influence on the corrosive action.

Many crude oils and products made therefrom are comparatively noncorrosive and are handled with ease. Some oils of high sulphur content cause more trouble. The choice of gray iron or steel for a given purpose depends a great deal upon the mechanical suitability of the respective metals and on their cost. Many tons of pipe, valves, fittings, and other gray iron equipment are used in the oil industry.

Gray iron castings are used in handling natural gas and in the manufacture and handling of artificial gas. Here again mechanical suitability and cost are the governing factors in choice between iron and steel, since the corrosion problems as a rule are handled equally well by either type of material.

Sulphuric acid has been termed the backbone of the chemical industry. It is manufactured by two processes, the chamber process and the contact process. In either of these processes, where the acid is 60° Baumé or over and is not extremely hot, it may be handled satisfactorily in cast iron. An exception occurs when the acid must be of high purity, and a trace of dissolved iron would be objectionable. However, dilute sulphuric acid attacks gray iron rather rapidly. Since strong sulphuric acid is deliquescent, strong acid in cast iron lines and equipment should be kept away from air. Leakage must be avoided carefully or severe corrosion may result.

The strong dense grades of iron comparatively low in total carbon and silicon usually are the most acid resistant. Special types of cast iron have been devised for acid and other corrosive services. The high silicon irons contain about 14% silicon and are quite resistant to dilute as well as concentrated acids.

While the high silicon irons possess excellent corrosion resistance to many media, their fragility and brittleness are a source of annoyance and trouble. They are difficult to cast and are almost unmachinable. The new austenitic cast irons possess

⁴H. O. Forrest, Corrosion of Cast Iron, Proc., A.S.T.M., 1929, pt. II, v. 29, p. 128.

fairly good resistance to most concentrations of sulphuric acid. These irons usually contain 12-20% nickel, 4-7% copper, and up to about 2% chromium.

Nitric acid production ranks next to sulphuric acid production in acid manufacture. Strong nitric acids and mixtures of nitric and sulphuric acid (mixed acid) attack gray iron slowly. Dilute nitric acid attacks gray iron rapidly. High silicon iron is resistant to both strong and dilute acids. Strong hydrochloric acid is not handled successfully in gray iron or the alloyed irons.

Gray iron is used widely and successfully in the handling of caustics and alkaline solutions. Even strong boiling caustic solutions attack gray iron only slightly. Gray iron equipment finds many applications in alkali manufacturing establishments, being used for caustic fusion kettles. Iron or steel is used for alkaline liquors according to the physical characteristics required. The high nickel, austenitic cast irons are even more resistant to caustic and alkalies than is ordinary gray iron; in fact, some grades containing about 20% nickel (with or without other alloys) are hardly tarnished by boiling caustic or lye.

Special cast irons used for corrosion resistance have been mentioned. The high nickel, austenitic irons have been found resistant to most sulphuric acid, salt and alkaline solutions. The corrosion resistance of the austenitic irons is superior to that of gray irons in all solutions in which they have been tested. Their range of application is rather wide. Due to this and fairly good casting properties and reasonable machinability, the austenitic irons are growing rapidly in popularity.

The 14-15% silicon irons have very high resistance to many types of acid corrosion, except hydrofluoric acid and strong hydrochloric acid. Their rather high corrosion resistance to many fluids and gases is offset by their fragility and high production costs.

High chromium cast irons (15-35% Cr) have recently been produced and apparently will find a number of applications requiring corrosion resistance.

XIV—Heat Treatment of Cast Iron—Cast iron is directly comparable to steel in its reaction to heat treatment, the only fundamental difference in the composition of the two materials being the presence of free graphite particles in gray cast iron. The heat treatment of cast iron may be broadly divided into 3 general classifications: (1) Annealing, (2) quenching, (3) special heat treatment.

Annealing—(a) *Relieving Internal Stresses*—The heat treatment resulting in the relieving of internal stresses is commonly called aging, normalizing, or mild annealing. This can be accomplished by heating from 800-1000°F., holding at temperature from 30 min. to 5 hr. depending upon section size, and slowly cooling in the furnace. This treatment will cause only slight decrease in hardness, very little decomposition of cementite, and only slight change in the inherent strength properties of the metal.

(b) *Softening for Machinability*—The desire in some cases is to soften the casting in order to facilitate machining. A good deal of the production heat treatment of cast iron is of this class. The temperature range most commonly used is 1400-1500°F., although temperatures as low as 1200-1250° have been used satisfactorily. Highly alloyed irons are sometimes annealed at temperatures as high as 1800°F. In all annealing, care should be taken to prevent oxidation of the casting.

In general, softening for machinability is attended with a decrease in strength and amount of combined carbon and an increase in graphite content. Irons containing carbide forming alloying elements such as chromium are more resistant to annealing than the ordinary gray iron. Temperatures used for annealing of these irons are considerably higher.

Completely annealed ordinary cast iron may have Brinell hardness values from 120-130, whereas completely annealed alloy irons may have Brinell hardness values of 130-180, depending upon the composition.

(c) *Annealing White or Mottled Irons as Cast to Obtain Higher Strength Gray Iron*—In order to obtain commercially machinable irons of from 60,000-90,000 psi. tensile strength, irons white or mottled as cast are annealed to effect the decomposition of carbides into ferrite and graphite. Such irons are sometimes referred to as semimalleable and pearlitic malleable irons. They should not be confused with true malleable iron, which is composed of ferrite and rounded graphite particles called temper carbon. The total carbon in these special irons is usually held at from 2-2.8%. The silicon content depends upon the section, but does not exceed 1.8%. A typical annealing cycle for this material is as follows:

Heat to 1700-1750°F. and hold for 1½-3 hr. Cool to 1375° for 3 hr., then subject

to one of the following: (a) Oil quench and temper, (b) air cool, (c) cool slowly in furnace.

The Brinell hardness of this type of iron will vary from 150-400 according to composition and treatment. Alloying elements such as nickel, chromium, or molybdenum may be used. The resulting product has high strength with measurable ductility and good impact resistance.

(2) *Quenching and Tempering*—In order to increase wear and abrasion resistance of cast iron, quenching from above the critical temperature is employed. Common soft gray irons that have a coarse interlocking structure and a ferrite matrix are not materially improved by heat treatment. They do not harden satisfactorily, while tempering may or may not improve their strength. Heat treatment should be employed to make good cast iron better and not to attempt to make poor cast iron into a fair product. As in steel practice, the addition of alloys such as nickel, chromium, or molybdenum has a marked effect on the response to heat treatment.

To heat treat satisfactorily, graphite flakes should be small and well distributed, while the matrix should preferably be pearlitic or sorbitic. Graphitic carbon of cast iron suitable for heat treatment should approximate from 2-2½% and the combined carbon should range from 0.50-0.80%. Given these conditions, gray iron castings respond to quenching and tempering much in the same way as carbon tool steels. The hardness increases in direct relation to the rapidity of quenching from above the critical temperature. Softening after hardening proceeds uniformly as the tempering temperature rises above 350°F. Tempering below 350°F. has little effect on hardness or structure. The strength and impact resistance are definitely improved by tempering.

The hardening effect brought about by rapid cooling from temperatures above the critical point is usually accompanied by a deterioration in strength. This deterioration is immediately restored by tempering (Fig. 23). Thus by suitable hardening and tempering a definite improvement in strength properties can be obtained.

The casting should be heated for hardening very carefully. It should be heated slowly and uniformly to the quenching temperature, then held for a sufficient length of time to insure that all parts have received the maximum heat. A safe minimum is 30 min. for comparatively small castings. To promote economy of operation, if the castings are small and of symmetrical design, they may be preheated at from 300-500°F. in one furnace and then transferred to another furnace, held at the quenching temperature, with little danger of cracking. The quenching temperatures used on most irons in production at the present time are from 1450-1550°F. The quenching medium most commonly used is oil, although water is also used to a limited extent. Some castings may be quenched in air.

The composition of the material is largely governed by the requirements of machinability in the as cast condition and the response to heat treatment. The casting to be hardened usually is rough machined before hardening and tempering and is finished by grinding. Small amounts of growth occur on quenching and allowance must be made for this in leaving stock for finish grinding. Where strength and shock resistance are not of particular importance, the tempering operation may be omitted.

Cylinder liners for use in heavy duty internal combustion engines have been heat treated both in this country and in England to secure a marked increase in hardness and wear resistance. The Brinell hardness has been increased from about 225 to over 400. The wear resistance has increased in line with the increase in hardness.

In suitable thin sections, ordinary unalloyed cast iron is capable of being hardened by oil quenching from suitable temperatures. In thicker sections, it has been shown that an ordinary cast iron is not very susceptible to hardening by quenching in oil. The presence of alloying constituents such as nickel, chromium, or molybdenum increases the susceptibility to hardening. The alloying elements in cast iron, just as in steel, have the effect of increasing the depth of penetration of hardness and also increasing the degree of hardness obtainable.

An excessively high hardening temperature is accompanied by definitely inferior results both as to hardness and strength values. The lower quenching temperatures tend to produce the best results.

The metal may be annealed before hardening without appreciably affecting the response to quenching or hardening properties, provided coarse interlocking graphite is not present. Care should be exercised in respect to sudden changes in tempera-

ture both in heating and quenching, particularly where castings are irregular in section and where size is large. It should be remembered that cast iron is more fragile than steel.

Some alloy cast iron compositions can be hardened by removing red-hot castings from the molds and cooling the castings in air, or by reheating to above the critical temperature and air cooling. Such cast irons have a matrix that may be sorbitic or martensitic. Nickel-chromium and nickel-molybdenum irons have been used. The use of a low carbon iron (2.50-2.80 total carbon) with a manganese content of about 2% results in materially reducing the A₁ point so that the castings can be hardened by quenching in still air or in an air blast. Good results have also been reported on cast irons with manganese 1% and nickel 1-2%.

(3) *Special Heat Treatment*—(a) *Nitriding*—The nitriding process for cast iron has been in use for several years and considerable experimental work has been done. Parts requiring extremely high wear resisting properties may be economically nitrided. The nitriding process consists in subjecting the casting to temperatures of from 950-1100°F. in contact with anhydrous ammonia gas for a period of time ranging from 20-90 hr. Low total carbon, chromium-aluminum irons for nitriding purposes were originally developed somewhat similar to the steel used for nitriding. A number of other compositions have also been developed for nitriding. A typical cast iron used for nitriding is as follows:

Total C 2.61%, Si 2.58%, Mn 0.61%, S 0.07%, P 0.10%, Cr 1.69%, and Al 1.43%.

Nitrogen hardened cast iron has been used in the production of cylinder liners for various types of engines, compressors, and pumps. It is claimed that excellent wearing results have been obtained.

(b) *Flame Hardening*—Flame hardening is being used to a considerable extent on gray iron castings, particularly where a hardened surface is desired for wear resistance. A large proportion of automobile camshafts are made of cast iron and most of these are hardened on the cams by means of the acetylene flame.

XV—Welding of Cast Iron—For information on the welding of cast iron see page 220.

Malleable Iron

By H. A. Schwartz*

Description of Malleable Iron—The production of malleable cast iron consists of two distinct steps. The first is the production of white iron castings which are brittle and hard. The second step is the annealing or graphitizing of the white iron so as to secure a ductile product known as "malleable cast iron." The annealing or graphitizing changes the combined carbon to free carbon in the form of temper carbon.

The free carbon of malleable cast iron is chemically and crystallographically identical with that in gray cast iron, but differs greatly in form. The graphite of gray iron, formed near the freezing point, has the shape of fish scales. That of malleable cast iron, formed at lower temperature, is crumpled up into nodules.

Malleable cast iron consists almost entirely of ferrite and carbon. Gray cast iron contains usually much pearlite and sometimes either ferrite or cementite.

Melting Furnaces—For the production of high grade malleable iron castings, that is, for castings with high tensile strength and elongation, the reverberatory type of furnace is used for melting. In this country the air furnace is used. This is often coal fired, either by hand or more often mechanically by means of pulverized coal. There are also some oil fired installations. The electric furnace is now being used either alone or in duplexing or triplexing.

Sectional views of a typical air furnace are shown in Fig. 1. The furnace walls are of firebrick, supported and inclosed by cast iron side and end plates. The hearth A is built of silica sand. Coal is burned in the firebox B; the air is forced through the fire by a blower discharging into the ash pit C; the ash pit doors D are kept closed. Air is also admitted through the tuyeres E, to aid in the combustion of the gas and in forcing the flame over the front or firebridge wall F. The roof of the furnace consists of a series of removable firebrick arches or bungs supported in cast iron frames. A sufficient number of these are removed to permit the introduction of the melting stock.

If pulverized coal or oil is to be used the firebox is replaced by a combustion chamber into which the burner points through an opening in the head wall near the roof.

Recently furnaces have been developed, working on the general principle of an air furnace, in which the entire hearth and roof are modified into a cylindrical structure rotating about a horizontal axis. In such furnaces that part of the cylindrical hearth which is above the level of the metal becomes highly heated. As the hearth rotates this hot refractory is carried below the surface of the metal imparting its heat thereto. The net effect is hotter iron for a given roof temperature. These furnaces are commonly used with recuperators furnishing air for combustion at about 450°F. Recuperators have also been found economical on air furnaces of the stationary type.

The air furnace is used for high grade malleable cast iron because it is possible to secure a more uniform composition of metal than with the cupola furnace.

In Europe, particularly in Germany, the open hearth furnace is used for the production of high grade malleable iron. One reason for using the open hearth furnace is that fuel is not available for the air furnace.

Air Furnace Charge—The charge used in the furnace consists of sprue, pig iron, malleable scrap, and steel scrap. The sprue is charged first, the steel and malleable scrap are charged on top of the sprue, while the pig iron is charged last.

Duplex and Triplex Processes—Considerable white iron for use in making malleable iron is produced by the duplex and triplex processes. In the duplex process, the iron is melted in the cupola, using a large percentage of steel in the mix so as to obtain a low carbon content, and is then introduced into the electric furnace. Steel additions may be made in the electric furnace where a final adjustment of composition is made and the desired temperature attained. In the triplex process, the charge is melted in the cupola and a portion of the resulting metal is treated in the Bessemer converter to reduce carbon. The final step consists of mixing in the electric furnace the necessary amounts of cupola metal, liquid steel, and alloys to give the desired composition. Duplexing with the use of cupolas and air furnaces

*Manager of Research, National Malleable and Steel Castings Co., Cleveland.

has been practiced both in the U. S. and abroad. There is also a limited use of cold melting in electric furnaces.

Cupola Furnace—The cupola furnace is used for malleable iron castings of lower tensile properties than are secured by melting in the reverberatory furnaces. Malleable pipe fittings come under this classification. Decreased tensile strength is not necessarily a detriment for such purposes. It is claimed that such iron as is made in the cupola produces fittings freer from leakage, at as high pressure, than lower carbon fittings. Advantages in machinability and freedom from galvanizing difficulties are also considered to exist. The latter advantage is probably due to a rather low phosphorus content.

Fig. 1—Sectional Views of an Air Furnace.

Composition of Malleable Iron—The composition of the white iron produced by any of these processes is adapted to the desired purpose. Any physical property of malleable is that of the metal body through which the carbon is scattered modified by the presence of that carbon which in effect acts like so many holes. The properties of malleable cast iron are therefore largely controlled by the amount of carbon present.

For various purposes the carbon may be as low as 2.00-2.10 or as high as 2.90-3.00% (or even more). In general high carbon makes the metal weak and less ductile, but makes the castings sound and of better surface. Many believe that increased carbon is favorable to increased machinability.

In high carbon iron the silicon is kept low, and in low carbon iron it is kept high in order to secure the most desirable properties. Silicon may be as much as 1.20-1.30% in small, low carbon castings or as low as 0.50 or 0.60% in large, high carbon castings.

In special cases, particularly when cross sections of castings are not too thick, the practice of dropping the carbon well down toward 2% and raising the silicon to as much as 1.6% has been advocated and to some extent practiced. Such irons can be made in air furnaces but are particularly adapted to melting in electric furnaces, often of the rocking indirect arc type or in the rotary air furnace. In electric melting particularly the charge is frequently largely steel scrap, petroleum coke and ferroalloys. If the carbon is dropped so far that in the presence of the existing silicon the iron is no longer eutectiferous the resulting products can no longer be classified as cast irons. They have certain analogies to malleable iron but also certain essential differences and should probably be called steel.

The manganese and sulphur go up and down together; manganese around 0.25% and sulphur around 0.05% may be encountered or manganese around 0.40% and

sulphur around 0.14%. Phosphorus is almost always below 0.20% and may go down to 0.100% or less.

Annealing Malleable Cast Iron—The purpose of annealing is the destruction of all combined carbon in the casting by converting it into graphite. The free, massive cementite can best be completely broken up above the critical point (A₁). The excess carbide which exists when cooled as pearlite must be decomposed below A₁.

The castings are annealed by packing in iron pots, sometimes using a packing material such as sand, cinders, or mill scale to support the castings. The pots are then placed in furnaces and heated in accordance with a predetermined cycle. As a general rule, the annealing furnace is brought up to temperature as rapidly as possible.

A typical annealing cycle for a stationary batch type furnace is as follows:

Time heating to 1500°F.	45 hr.
Time holding above 1500°F. (max. 1650°F.)	50 hr.
Time cooling	60 hr.

In some foundries and for some castings it has been found possible to do away with packing material in the annealing process.

Continuous car type furnaces are frequently used for the annealing of malleable iron castings. The castings are loaded in pots on cars and the cars move slowly through the furnace. The various zones of the furnace are maintained at the required temperatures. Car bottom type batch furnaces are also in use which conserve time by conserving the heat content of the furnace structure. In these furnaces the car is first inserted in a furnace at maximum temperature and then removed to a second furnace which is at the proper temperature for completing the reaction. Considerable savings of time are made by accelerating the heating and cooling rates and by making it possible to remove a charge at a temperature at which it could not be handled in a stationary bottom furnace.

Where small lots of castings are heat treated in accurately controllable furnaces, and especially when high silicon metal is used, great modifications are possible in the direction of a shortened anneal.

Using the most modern furnace designs, dispensing with pots and with the most careful control in the manufacture of the hard iron an annealing time of around 50 hr. total time can be commercially maintained. In smaller units in which temperature gradients may be less this could be reduced somewhat further. Highly reputable persons report operating times around 30-36 hr. A time around 70 hr. is readily attained even in large continuous units in which the temperature gradient in pots is an important consideration. The saving of time in all these cases is made by cutting out time wasted in needlessly slow heating and cooling, cooling to too low a temperature or waiting for cold parts of a charge to come to temperature.

It is always important to remember that the complete elimination of pearlite is the most time consuming factor of an annealing cycle. If even small amounts of pearlite are tolerable or perhaps desired, a disproportionately large time saving may be possible. Those who speak of reducing annealing cycles do not always clearly differentiate between making malleable castings and making pearlitic malleable castings.

Some very short cycles, 15 to 18 hr., have been reported. In considering such a process it is always necessary to take account of the size of charge which can be handled and maintain uniformity of result, whether the required chemical composition is safe from the viewpoint of occasional or frequent occurrence of very poor iron and whether the product is actually as free from pearlite as is required for good machining. Castings have in fact been quite satisfactorily annealed in as little as 3 hr. by methods not to be recommended for tonnage production.

Fig. 2—Magnetization Curves for Various Malleable Irons.¹

¹Reproduced from the "Symposium on Malleable Iron Castings," published by the A.F.A. and I.S.T.M.

Any maximum temperature up to about 1800°F., where the castings become too soft to hold their shape, may be used. With increase in temperature comes a great decrease in the time to break up the cementite of white cast iron. The slow cooling or holding under 1400°F., necessary to break up pearlite, can not be so much accelerated but under favorable conditions a total annealing cycle of 30-48 hr. has been used. This is often done with special forms of electrically heated furnaces in which the castings and heating units are sealed up together in an air tight chamber. The use of tubes of scale resisting alloys, heated internally by gas flames and possibly also by oil or powdered coal flames, has also found favor as a means of heating a charge in a completely sealed chamber. The result is equivalent in principle to annealing electrically. Large lots of castings can not be heated fast and uniformly enough to secure the fastest annealing time. Especially for the low carbon, very high silicon type of metal continuous annealing furnaces operating without packing have been advocated by some in order to produce an extremely short annealing cycle. Although a reduction in annealing time is highly desirable it must be remembered that the more elaborate equipment required sometimes outweighs in money value the increased production and that most of the quick annealing products and processes are more closely limited in application and operation than the slower processes.

Metallurgical Principles—Malleable cast iron of acceptable quality is intended to consist entirely of ferrite and "temper" carbon which is graphite in round nodules instead of in flakes as in gray iron. This result requires that the original casting must be entirely free from flaky graphite such as is produced during freezing. To accomplish this the composition of the melt must be kept within certain limits, mainly as to carbon and silicon. The cross section of the casting also plays a part because it determines the cooling rate in the mold which has an effect on the amount of graphite separating. Heavy sections must be lower in carbon and silicon than light sections.

During annealing iron carbide "cementite" dissolves at the surface of contact of cementite and austenite; the carbon migrates in some form the surface of graphite nodules and there crystallizes out. Somewhere in the process, cementite is dissociated into iron and carbon.

Under most operating conditions the rate of migration determines the annealing rate. If that is so, annealing should be accelerated by any process which increases the number of spots of graphite in a unit volume, for this reduces the distance which the carbon has to travel. This number can be altered to a considerable degree by changes in melting and heat treating methods. Some elements accelerate annealing, particularly Si, Al, Ti, Zr and U and to a less extent Cu, Ni, P and probably Co. Others retard annealing, particularly Cr, Mn, V and to some extent Mo among the metals, and S, Se and Te among the nonmetals. Sn, Ce and La are also regarded as possible retarders. No one yet knows the mechanism by which these elements act. Like all chemical reactions graphitization goes on faster the higher the temperature. The process can not be completed above the critical point, for considerable carbon dissolves immediately above that temperature and can not be separated in the free state except by very slow cooling or long holding. Of course the completion or "second stage" of annealing below the critical point cannot be hurried by raising the temperature for which the A_1 point is a ceiling.

Unfortunately many of the factors which will hurry annealing are not favorable to the safe maintenance of high quality. They therefore frequently involve additional care and expense if an acceptable product is to be turned out.

Use—Malleable cast iron is used for castings which must withstand shock and where gray iron would probably fail because of low ductility. A condensed list of malleable iron castings is given in Table II.

Alloyed Malleable Iron—Malleable iron is understood to be an entirely ferritic material. Maintaining that limitation, only copper and somewhat problematically molybdenum* have so far come into any prominence. Copper somewhat facilitates annealing and improves the strength and to some extent, the ductility of malleable when present in an optimum amount of about 1%. Such alloys are capable of precipitation hardening with considerable increase in strength, and indentation hardness and little effect on ductility. It is reported that copper benefits high carbon malleable more than low carbon in the annealed condition.

*See the article in this Handbook, Pearlitic Malleable Iron. The information on copper is from Lorig and Smith, Trans., A.F.A., 1934.

¹These chemical compositions are not to be taken as specifications, because the specifications for mechanical properties can be met by a number of compositions, depending on foundry practice and conditions.

²The longer range of values for grade 35018 material is in part due to more frequent investigations.

The tensile strength of iron containing about 2.35% total carbon was not materially altered by any amount of copper up to 2.68% although the yield point was raised 6000 psi. The elongation was raised from 14.5-22.2% by 0.63% copper and then fell off to about 16%. In iron containing about 2.70% carbon the tensile strength was raised progressively with increases of copper by 14,000 psi. for 2% copper, the yield point was raised 16,000 psi. and the elongation was not uniformly affected. Precipitation hardening may raise the tensile strength by from 2000-10,000 psi. depending upon other conditions, the yield point by somewhat greater amounts with little and variable effect on elongation. The endurance ratio is not materially altered by copper so that the increased tensile strength involves corresponding increments in fatigue resistance. As annealed the Charpy value is increased by the presence of copper.

The information as to the effect of molybdenum on ferritic malleable is as yet not sufficiently conclusive to permit of a survey. The concentrations of molybdenum which could be used within this limitation are, of course, limited. The use of an increased silicon content in the presence of molybdenum seems to have some merit.

A strengthening effect on malleable due to small amounts of aluminum has been reported. The method has apparently not been introduced into practice and is generally regarded as dangerous due to the possible formation of "primary" graphite during freezing.

Table II

**Classification of Industries, with Condensed List of Products, in Which
Malleable Castings Are Used¹**

Agricultural Implements

Plows, tractors, harrows, reapers, mowers, binders, cultivators, rakes, spreaders, dairy and poultry equipment, presses, tools, pumps, wagons, fence parts.

Automobiles

Parts for frame, wheels, springs, brakes, motor transmission, axles, steering gear, body, accessories.

Boilers, Tanks, and Engines

Boilers, tanks, fittings, engine parts, out-board motors, Diesel engines.

Building Equipment

Hardware for windows, doors, garage equipment, awning hardware.

Conveyor and Elevator Equipment.

Chains, buckets, pulleys, rollers, cranes, hoist, fittings.

Electrical and Industrial Power Equipment

Motor and generator parts, pumps, stokers, electric locomotives and tractors, steam specialties, outlet and switch boxes.

Hardware and Small Tools

Pneumatic and portable tools, miscellaneous tools, saddlery, hardware, table and kitchen utensils.

Household Appliances

Stoves, sewing machines, refrigerators, washing and ironing machines, vacuum cleaners, dishwashing machines, oil burners, electric fans and toasters, radios.

According to the Department of Commerce, there are about 150 plants in the industry, with an estimated annual capacity of 1,350,000 tons.

¹Reprinted from the "Symposium on Malleable Iron Castings," published by the A.F.A. and A.S.T.M.

Machine Tools

Lathes, planers, shapers, grinders, screw machines, gear cutters, drills.

Machinery for Special Uses

Textile, cement, rubber, shoe, mining and quarrying, grinding, forging, foundry, bakery, woodworking, bottling, ice, laundry industries.

Marine Equipment

Anchors, chains, capstans, fastenings, towing bits, hardware.

Metal Furniture and Fixtures

Stoves, beds, desks, filing cabinets, shelving, hotel supply equipment.

Municipal, State and Public Service

Manhole covers, posts, guard rail equipment, highway markers, transmission and telephone line fittings, electric railway fittings.

Pipe Fittings and Plumbing Supplies

Elbows, unions, reducers, flanges, valves, bolts, nuts.

Railroads

Wide variety of parts for construction of locomotives, freight and passenger cars; guard rails, miscellaneous.

Road and Contractor's Machinery

Rollers, excavators, cranes, hoists, tractors, graders, scarifiers, mixers, pavers.

Toys and Specialties

Sleds, wagons, automobiles, bicycles, carriages, gun parts.

Pearlitic Malleable Iron

By H. A. Schwartz*

Malleable iron was originally valued mainly because of its ductility and machinability. Of late, uses have suggested themselves which require increments in strength, yield point, or fatigue resistance even at a sacrifice of elongation or ease of cutting. Various processes have been suggested for making what is probably best called, generically, "pearlitic malleable," even though the "combined" or "agraphitic" carbon is sometimes present as sorbite or even martensite.

"Pearlitic malleable" is now intended to be understood as designating white cast iron subsequently graphitized by heat treatment so as to intentionally leave significant amounts of carbon in the "combined" or "agraphitic" form.

These metals can be subdivided into groups according as to whether:

- (a) They are produced by stopping the graphitizing operation before all the agraphitic carbon is converted into graphite or by completely graphitizing and then recombining some carbon.
- (b) When produced by incomplete graphitization the retention of agraphitic carbon is brought about mainly by the shortening of the cycle or by the presence of alloying elements.
- (c) Their metallography has certain particular characteristics as to kind and distribution of given constituents.

The methods of melting, molding, and casting are in any event exactly the same for pearlitic irons as for ordinary malleable except for the introduction of alloys if these are to be used. It is doubtful whether in the customary amounts alloying elements have any effects of themselves on the properties of pearlitic malleable. They are used primarily to facilitate the control of combined carbon which would be possible but sometimes more difficult without them. Some processes carried out to give a matrix of particular character, such as spheroidizing, go on so slowly that in unalloyed malleable the destruction of agraphitic carbon by graphitization would outrun its conversion into the desired form and a retarder of the graphitizing reaction is advantageous.

The usual retarding elements are manganese in an amount up to 1% more than the concentration otherwise suitable for normal malleable, chromium often in low concentration of 0.10-0.25% but occasionally suggested higher, and molybdenum seldom up to 1% and frequently about ¼% or even less. Some see virtue in the combined use of rather large amounts of retarders and additional accelerators, as for example, silicon with chromium or molybdenum.

All the interrupted annealing processes begin with an equivalent of the first stage of annealing of malleable cast iron. The alloy is graphitized as far as it will go at a temperature somewhat above the critical. From there on the process depends upon whether laminated pearlite or a spheroidized structure is desired in the matrix. In the former case the metal is cooled through and below the critical range at a rate which will be slow enough to form laminated pearlite and also slow enough to permit the desired degree of graphitization to go on accompanied by the liberation of the desired amount of temper carbon. Such rates may be from 10-100°F. per hr. depending on the metal and the desired properties. The first separation of ferrite in such a heat treatment is usually around the temper carbon producing a so-called "bull's eye" structure consisting of temper carbon surrounded by a ring of ferrite all embedded in pearlite.

Alternatively the metal may be cooled fast enough through and well below the critical range to produce martensite (occasionally only sorbite) and then spheroidized for such a time as will give the desired amount of agraphitic carbon. It is recommended that any metal intended for the manufacture of pearlitic malleable should be moderately low in carbon.

Pearlitic malleable may be made from ordinary malleable either by reheating above the critical point for a time sufficient to saturate all the iron with carbon to a uniform concentration and then proceeding as for the interrupted anneal methods. This procedure is uncommon in practice.

When malleable iron is heated not far above the critical, recombination of carbon takes place first at the grain boundaries. Suitable choice of temperature

*Manager of Research, National Malleable and Steel Castings Co., Cleveland.

thus permits producing a structure consisting of a network of metal containing agraphitic carbon surrounding ferrite grains. By further heat treatment the network can be made into anything from martensite to granular pearlite. Especially

Fig. 1—Temper carbon in spheroidized matrix produced by controlled rapid cooling of high manganese (about 0.75%) white irons completely graphitized to equilibrium above A_1 , followed by spheroidizing draw (100x—nital).

Fig. 2—Bull's-eye malleable produced by normal graphitizing cycle applied to high manganese (about 0.70%) hard irons (100x—nital).

Fig. 3—Granular ferrite and pearlite in high silicon and chromium white iron with normal graphitizing heat treatment (100x—nital).

Fig. 4—Sorbitic carbon at grain boundaries produced by reheating malleable iron just above A_1 then quenching and tempering (100x—nital).

good combinations of strength, ductility and shock resistance are claimed for this distribution of ingredients.

It may be reliably anticipated that all pearlitic malleable is stronger, less ductile and less machinable than malleable itself. It is often less shock resistant but this rule is not without exception. Tensile strengths of 90,000 psi. and perhaps even of over 100,000 psi. are obtainable at a sufficient sacrifice of elongation. Elongation will range downward from that of malleable iron to as low as 2 or 3%, depending upon how much strength was to be retained. The claim is made that spheroidized "pearlitic malleable" is more ductile for a given strength than iron containing laminated pearlite.

The fatigue ratio of all forms of pearlitic malleable is probably near 0.50. The Brinell number may be anything above that of malleable. It is easy to produce metal of a Brinell hardness number well above 300, but machinability usually sets a limit at around 230 and even at 190 machinability is for many products rather difficult.

There has not yet been sufficient critical review of data on the physical properties of these alloys to warrant more definite statements for a handbook.

It has also been found possible to alloy ordinary malleable iron with enough chromium and aluminum to permit of nitriding and it is understood that the product is "pearlitic malleable". This is quite suitable for the purpose for no great ductility would be useful in a nitrified object.

Graphitized pearlitic products of a composition such that they should be classified as derivatives of steel rather than of cast iron have found a few important applications but no systematic survey of that field is yet possible.

Physical Testing of Tool Steels*

I—Introduction—This article lists and classifies nearly all of the physical tests that might be applied to a tool steel. The practical value of many of them is questionable, but descriptions are included to make available information on all methods.

The object of this article is to help consumers select tests best suited for a given purpose. They should first definitely determine what may be learned from these tests and then choose those most practical and easily correlated with service.

II—Chemical Tests—See page 682 for methods on the chemical analysis of steels.

III—Spark Tests—See page 773 for an article on Spark Testing.

IV—Fracture Tests—The fracture test is a means of examining steel visually for two purposes, (1) To detect internal defects, and (2) to determine fracture grain size. The test will therefore be discussed under these two headings.

1. *Fracture Tests for the Determination of Internal Defects*—This test may be easily misinterpreted by inexperienced observers, so the following guide for proper interpretation is offered.

Fracture of Annealed Steel—Annealed tool steels may be fractured by nicking on one side followed by striking the end close to the nicks with a sledge hammer. The bars or specimens are usually supported on an anvil to avoid danger from flying pieces. The conditions described below may be observed from annealed fractures.

Decarburization—Decarburization is determined by the difference in grain size between outer edges and interior of the specimen. The decarburized zone will exhibit a grain larger in size and brighter in color than the interior of the specimen. All hot rolled bars possess a decarburized surface so that acceptance of material is based on whether the amount present may be detrimental (Fig. 1).

Pipe—Piped steel caused by shrinkage cavities in the ingot will be recognized from an actual discontinuity at or near the center of the specimen. When this condition has been largely removed a coarser or brighter grain may appear in the center (Figs. 2 and 3).

Bursts—Ruptures produced by forging or rolling somewhat resemble pipe. Distinction may sometimes be made from the shape of the defect or from deep etch tests.

Flakes—Flakes will appear as short ruptures or bright spots in longitudinal fractures. When fractures are made through, rather than across the flakes, the bright colored spot will appear somewhat conchoidal in form. Care should be taken not to confuse this defect with areas which have been made bright by rubbing during fracturing or with sections elongated during breakage. Flakes in water hardening steels are usually detrimental. In other types the effect of their presence should be determined before rejection (Fig. 7).

Woody Structure—Fractures taken in the direction of rolling or forging are often of a fibrous appearance. Since all steels are of a heterogeneous nature the degree of such fibrous appearance will depend upon several factors, such as composition, cleanliness; amount, and direction of working. Steels so highly alloyed as to be of a segregated nature; such as high speed steel, will quite often show a fibrous structure to varying degrees, especially in larger sections. An interpretation of the effect of the fibrous structure can only be made with a full knowledge of the general characteristics of the steel in question. Fig. 8 shows a woody structure.

Fractures of Heat Treated Steels—Heat treated specimens may be nicked with thin cut off wheels to assist in obtaining satisfactory breaks. When breaking, precaution should be taken to prevent injury from flying fragments. Any of the conditions encountered in the fractures of annealed steel can be recognized to better advantage in heat treated specimens. It is often preferable in examining heat treated fractures for internal defects to cut a relatively thin disc and break this in the direction of rolling or forging so that the defects are examined in the elongated condition.

Penetration of Hardness—The penetration of hardness in carbon or low alloy steels may be determined by the variation in grain size from surface to center in

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stots, Chairman; A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Willis, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, O. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

transverse fractures. A more certain method of measuring penetration is by grinding and etching the cross section of the piece. Tests of penetration are taken up more in detail in Section VIII in which illustrations are shown on both fractured and deep etched sections.

2. *Fracture Tests for the Determination of Grain Size*—In the annealed condition,

Fig. 1—Decarburized surface. Fig. 2—Pipe. Fig. 3—Coarse center grain result of pipe. Fig. 4—Proper grain for high speed steel. Fig. 5—Fine grain carbon steel. Fig. 6—Coarse grain.

highly alloyed steels show a finer grain than carbon or low alloy steels as shown in Fig. 4, 5 and 6.

The grain size in the treated condition will vary with the type of steel as regard composition, inherent characteristics, the hardening temperature, time, and the quenching medium.

The visual grain size in a fracture is usually a reliable indication of the correctness of heat treating. However, there are exceptions especially in high speed steels, so the fracture test should be supplemented by microscopic examination (Section VII).

The arbitrary standards are generally used for the quantitative determination of fracture grain size. These standards consist of fractured $\frac{1}{8}$ in. dia. test samples, each uniform throughout its section, and numbered from 1 to 10, number 1 being an extremely coarse fracture, ascending numbers becoming finer grained in uniform steps, 10 being extremely fine and silky. Fracture grain sizes for No. 1, 5, and 10 of these standards are shown in Fig. 9.

Fracture grain size readings are made by comparing the unknown fracture with the standard and designating its grain size as the number of the standard fracture which it most nearly matches. If the unknown fracture falls midway between two of the standards such as for instance 8 and 9, it is rated as a half number, such as 8½.

V—Hardness Testing
—Descriptions of the Brinell, Rockwell, Scleroscope, Monotron, Vickers, and file hardness testing methods, as well as Hardness Conversion Data, are given on pages 112-128.

For testing medium and low hardness tool steels, those machines using the principle of ball impression are preferable, while for testing high hardness tool steels, the diamond point machines are generally used. The file test is used on hardened tool steels only.

V-a—Hardness Testing at Elevated Temperatures—See p. 129 in this Handbook, for an article on this subject.

VI—Macro Etching of Tool Steels—Procedure for deep etch testing is given on

Fig. 7—Flakes. Fig. 8—Woody structure. Fig. 9—Fracture grain sizes for specimen 1, 5, and 10, X5.

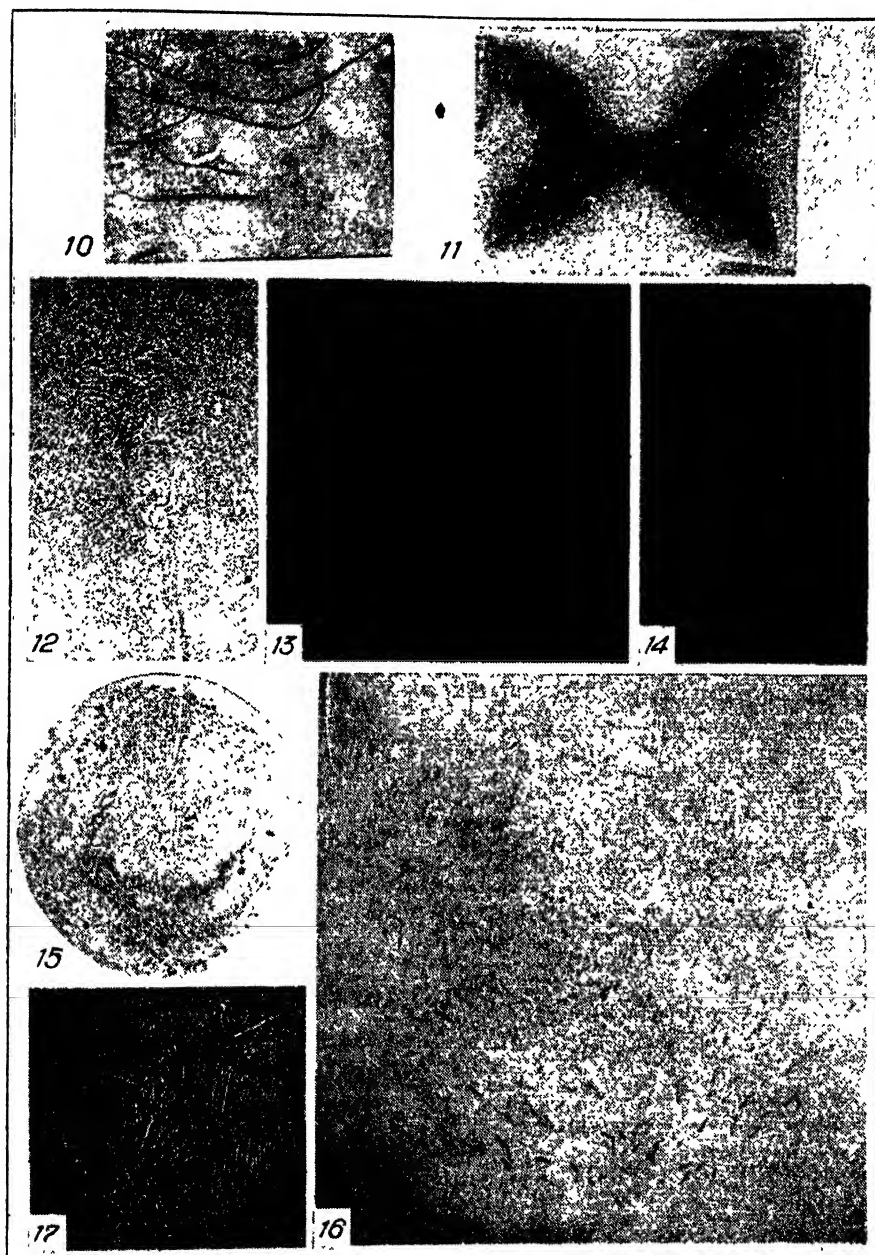

Fig. 10—Etching cracks. Fig. 11—Surface appearance and pattern effect. Fig. 12—Center porosity. Fig. 13—Pipe after etching. Fig. 14—Hammer burst after etching. Fig. 15—Unsond steel—blow holes and nonmetallic inclusions. Fig. 16—Internal cracks. Fig. 17—Dendritic structure.

page 726, consequently, this article will deal strictly with interpretation of the results rather than procedure.

The deep etch test reveals readily and quickly many of the characteristics of tool steel, but in some instances, further examination by standard testing methods is required to evaluate them properly. The knowledge that a piece of steel is dendritic or contains metallic and nonmetallic segregates is not sufficient evidence in itself on which to base definite conclusions of the properties of the steel. There is real value in the deep etch test when used to separate materials which are obviously defective from those which are not. It is easily made, but requires experience and judgment to interpret the results.

Cracks from Etching—Hardened or otherwise highly stressed steels should be sufficiently tempered before etching to prevent cracking because they may crack in the etching solution (Fig. 10).

Surface Appearance—Steels may etch with a comparatively smooth surface or with a highly rough or pitted surface, depending upon variables in manufacture, and composition. Therefore, a highly roughened surface is not necessarily detrimental (Fig. 11).

Irregularity in pitting may usually be attributed to one or more of the defects given below. Certain manganese, oil hardening types are more readily attacked by

Fig. 18—Pattern effect. Fig. 19—Coarse grain size as shown by etching. Fig. 20—Decarburization as shown by etching. Fig. 21—Hardened case shown by etching 1% carbon tool steel.

the acid and are often decidedly roughened without in any way being defective.

Center Porosity—Porosity may be the result of an actual discontinuity within the metal, in which case it is probably more proper to classify the defect as a pipe. Usually, however, the porosity is of such a nature that it is not visible until the specimen has been subjected to the etch. This condition can be found in widely varying degrees and the question of whether the steel should or should not be used is one of experienced judgment (Fig. 12).

Pipes and Bursts—Usually such defects are visible before deep etching. After etching it is often possible to distinguish between the two by the degree of sponginess surrounding the defect. Piped material usually shows considerably more sponginess than burst material (Fig. 13 and 14).

Unsound Steel—Numerous blow holes and nonmetallic inclusions visible as the result of the deep etch are usually indicative of both gases and oxides being distributed throughout the steel at the time of casting (Fig. 15).

Nonmetallic Inclusions and Metallic Segregates—In killed steels, nonmetallic inclusions usually appear as pits and must not be confused with pits occurring from the etching out of metallic segregates. When nonmetallic inclusions are suspected in highly alloyed steels which may contain metallic segregates, a comparison should be made of an annealed specimen and a hardened specimen etched alike. If the etching pits are the result of nonmetallic inclusions they will appear similarly in both the annealed and hardened specimens; if they are the result of a metallic segregate they will differ. Microscopic examination is preferable for determining their true character.

Internal Cracks—Internal cracks, sometimes called flakes or cooling cracks, can often be observed as the result of the deep etch test. These cracks are an actual discontinuity in the metal and, depending on their nature and distribution, may make the steel unfit for use (Fig. 16).

Dendrites—Etching often reveals a dendritic structure, which is the result of the crystallization characteristics of the ingot. Dendritic structure is not detrimental in most instances. The permissible degree depends on the application (Fig. 17).

Pattern Effect—Pattern effect is almost wholly the result of the crystallization of the ingot and generally results from that part of the bar which was the columnar structure of the ingot etching differently from that part which was the granular structure of the ingot. Should the steel contain considerable sulphide and silicate inclusions, then the area of contact between the columnar structure and the granular structure may be particularly noticeable. In the absence of large amounts of sulphides and silicates, the pattern effect probably is of no serious consequence (Fig. 18).

Grain Size—While the etch test is of no definite value in determining grain size, nevertheless the manner in which many specimens etch may indicate something of the grain size. Generally the larger the grain, the coarser will be the appearance of the etched surface (Fig. 19).

Decarburization and Carburization—Generally the areas which have been either decarburized or carburized will etch differently from the remainder of the specimen, chief difference usually being one of color. Decarburized parts will appear lighter in color and carburized parts darker (Fig. 20).

Hardened Case—In shallow hardening steels a contrast in color results between the case and the core by mild etching (Fig. 21).

Flow Lines from Forging or Rolling—A longitudinal section when subjected to the macro etching will often show flow lines due to the elongating of structural constituents. Such flow lines are always visible to a greater or less degree. They indicate the directions in which the steel was worked. Flow lines do not signify defective material (Fig. 22).

Surface Defects—Seams, laps, and cooling cracks, and other surface defects are revealed and exaggerated in the surface of bars which have been deeply etched (Fig. 23). Therefore, a short time etch is recommended.

Soft Spots—Soft spots which so often result when hardening carbon or low alloy tool steels can be readily distinguished by the macro etch test. The soft spots invariably etch in relief and are not so dark in color as the harder surrounding areas (Fig. 24).

Grinding Cracks—Grinding cracks can be easily distinguished by the standard macro etch and are usually identified by a pattern of some symmetry (Fig. 25).

VII—Microscopic Test—The examination of polished sections of tool steel under

the microscope is a common method used in connection with its inspection, the investigation of tool failures and various research problems.

Cutting, grinding, and polishing equipment required for this work is covered under "Preparation of Metallographic Specimens," on page 722. Etching reagents are given on page 170.

The avoidance of polishing pits and scratches in tool steels is not so difficult as with soft steel. Polishing pits are sometimes mistaken for inclusions and careful polishing is essential for best results. For the etching of tool steel specimens, the use of a 2-5% solution of nitric acid in alcohol is generally applicable. Somewhat stronger solutions may be used for highly alloyed types.

In the microexamination of tool steel, a microscope with a capacity up to 1000 diameters should be satisfactory for all ordinary requirements.

By examination under the microscope, it is possible to determine a number of factors which may affect the quality or performance of tool steel. Among these may be mentioned:

- | | |
|------------------------------|---------------------------------------|
| (a) Grain size | (d) Size and distribution of carbides |
| (b) Effect of heat treatment | (e) Nonmetallic inclusions |
| (c) Structural constituents | (f) Segregations |

(a) *Grain Size*—The grain size may be considered as referring to the size of the austenite crystals which are formed when the steel is heated above its critical

Fig. 22—Flow lines on longitudinal section. Fig. 23—Surface defects—rolling laps. Fig. 24—Soft spots. Fig. 25—Grinding cracks on hardened die steel.

points. These grains may be observed under the microscope in steels that can be made austenitic at room temperatures. It is possible by certain heat treatments to develop grain structures that are a record of the austenite grains that existed at the previous high temperature to which the steel was subjected. (Fig. 26 and 27.) The well known McQuaid-Ehn test is a method for the study of the grain size under a given set of conditions. It is usually limited to carbon or low alloy steels and grain size observed for comparison with a standard or chart by examination of the case at 100-150 diameters. Grain size, factors affecting it, and its relation to physical properties are of importance with some users of carbon and low alloy tool steels.

(b) *Effect of Heat Treatment*—While the most common method of checking the prior heat treatment of tools is by the examination of hardened fractures, microexamination of hardened structure is more accurate. In cases of steels

Fig. 26—Case structure of coarse grained carbon tool steel (0.90% C). Carburized at 1750°F. So-called normal steel. 125X. Fig. 27—Same as Fig. 26, but of so-called abnormal steel. 125X. Fig. 28—Large martensitic needles in overheated manganese oil hardening tool steel. 600X. Fig. 29—Same as Fig. 28, but properly hardened. 600X. Fig. 30—Large austenitic grain size from over heating high speed steel when hardening. 660X. Fig. 31—Normal austenitic grain size in hardened high speed steel not tempered. 600X. Fig. 32—Carbon tool steel (1.20% C). This steel was not fully annealed so shows lamellar pearlite and traces of segregated cementite. 600X. Fig. 33—Same as Fig. 32, but fully annealed with carbides in a spheroidized condition.

developing a largely martensitic structure when hardened, the size of the martensitic needles may be considered a measure of the austenitic grain size following a given heat treatment. A structure with enlarged martensitic needles is associated with overheating (Fig. 28). On the other hand, partial or complete absence of martensite and the presence of numerous small undissolved carbides may indicate an underheated condition. The relative proportion of austenite, martensite, and troostite sometimes throws light on the degree of tempering (Fig. 29).

Properly hardened or overheated high speed steel as quenched from the usual hardening temperatures and high carbon, high chromium steels when overheated develop an austenitic structure. Observation of the size of the austenitic grains is useful when investigating the heat treatment or physical properties of these types (Fig. 30 and 31).

(c) *Structural Constituents*—A large proportion of tool steels have a comparatively high carbon content and represent eutectoid or hypereutectoid compositions. In such steels, carbide forms predominate as the structural constituents. These may refer to pearlite, cementite, austenite, martensite, troostite, sorbite or carbide segregate (Fig. 32). Ferrite may exist as a minor constituent in the lower carbon (hypoeutectoid) tool steels. It also is the principal constituent of the matrix observed in the examination of the structure of annealed tool steels when the carbides are present in the spheroidal condition (Fig. 33).

It may be desired to identify or estimate the proportion of structural constituents of tool steel in the annealed and hardened condition and sometimes in the hot worked condition. This work is done by the examination of longitudinal or cross sections at usually 500 diameters or more.

(d) *Size and Distribution of Carbides*—In hypereutectoid carbon tool steels and the more highly alloyed tool steels, such as high speed and the high carbon, high chromium types, size and distribution of the carbide segregate have a bearing on quality and may be a factor in tool failures. It requires considerable experience on the part of the observer to know what to expect as to uniformity and what is objectionable as to carbide network and segregation in various sized sections. Inspection for carbide *distribution* is made at about 100 diameters (Fig. 34, 35, and 36). *Size* of carbides in alloy or carbon tool steels is preferably observed at 500 diameters or more.

(e) *Nonmetallic Inclusions*—Among the nonmetallic inclusions that may exist in tool steels are slag or refractory inclusions, and others that represent deoxidation products and various silicates.

Examination for nonmetallic inclusions may be made by examining unetched polished longitudinal sections at 100 diameters or more. In some cases when the steel tends to pit readily in the polishing, inclusions show better if polished in the hardened condition and after the specimens are lightly etched in nital (Fig. 37).

(f) *Segregations*—Carbide segregation is the most common kind that may exist in tool steels. It exists in varying degrees in the highly alloyed types such as high speed, and high carbon, high chromium steels as referred to under paragraph (d) above, covering carbide distribution. Carbon and the low alloy tool steels may show carbide segregation to a lesser extent. Excessive carbide segregation is objectionable as it may be a cause of tool failures or difficulty in machining. Carbide segregations may be observed to advantage by the examination of longitudinal sections at magnifications of 200 diameters or more.

VIII—Hardening Tests—In devising and interpreting tests for the hardening characteristics of tool steel, it is important to consider the type of steel, its application and method of hardening employed.

1. *Penetration of Hardness, Shallow, and Medium Deep Hardening Steels*—Penetration of hardness is the depth to which a tool steel will show full hardness upon quenching. The carbon and carbon-vanadium steels are typical shallow hardening and the line of demarcation between the hard case and the relatively soft core being quite distinct. Starting with the carbon steel increasing hardness penetration can be obtained by the addition of small amounts of such elements as chromium, manganese, silicon and molybdenum. As the hardness penetration is increased by the addition of such elements, the line of demarcation between the case and the core grows less sharp, and in the extremely deep hardening steel is replaced by only a slight drop in hardness toward the center.

Tests for penetration are of most value in connection with the shallow and medium deep hardening types. Because of the wide difference in behavior of these types, no single test can be adapted to all. Consequently two types of test, one

for shallow hardening, and one for deeper hardening steels are here suggested.

For the shallow hardening types a very convenient test is the P-F test (Penetration-Fracture). This consists of hardening in brine four samples machined to $\frac{1}{4}$ rd. x 3 in. long, one each from 1450, 1500, 1550, and 1600°F., notching each in the middle and fracturing by impact. Then one-half of each piece is examined for the grain size of the case, by comparison with the standard described under Section IV. Penetration tests are made on the other half of each sample by grinding the fracture and smoothing it on No. 0, or finer, abrasive, etching three minutes in 1-1 HCl at 180°F. and measuring the hardness penetration in 64ths of an in.

Fig. 34—High speed steel with cellular carbide distribution. The original ingot structure was not fully broken up during hot working. 125X. Fig. 35—High speed steel with heavy carbide segregation. 125X. Fig. 36—Uniform carbide distribution in high speed steel. From section $1\frac{1}{2}$ x $\frac{1}{4}$ in. Bar stock. 125X. Fig. 36A—Same as Fig. 36, but from a 3x3 in. hob forging. 125X. Fig. 37—Large nonmetallic inclusion in high speed steel. 125X.

The P-F characteristic is then recorded as numerals. The first four numbers represent the penetration in 64ths, and the last four numbers the fracture grain size. The first number of each group represents the P-F results for a temperature of 1450°F. and the second number of each group represents the P-F for a temperature of 1500°F., and so on. Fig. 37A illustrates a typical test, the figures designating the penetration and fracture values determined for each specimen. The value of this test in showing the hardening characteristics of a plain carbon steel over a wide range of temperature is obvious.

Various precautions must be taken in conducting this test where results are to be strictly comparable. The original structure of the test pieces resulting from annealing or pre-treatments is important. For general comparisons, since most tools are made and hardened from an annealed bar, it is desirable to make the

test on annealed specimens, just as cut from the bar stock. If, however, it is the practice of the consumer to normalize or in some way pre-treat the tools before final hardening, the P-F tests should be made on specimens having these preliminary treatments in order to give an indication of the behavior in the finished tool.

Fig. 37A—Etched sections and fractures in P-F test on carbon steel.

For accurate results close control of the time cycle and temperature in hardening must also be maintained. Usually the specimens are so heated that the total time in the furnace is 25 min. for each temperature. These conditions can be realized with considerable uniformity by using a relatively large furnace, bringing it up to the final desired temperature, introducing the specimens and bringing them up to temperature without allowing the furnace to drop back.

Fig 37B—Block used in determining penetration for deep hardening steels.

For uniform results specimens should be quenched in a flush using 10% brine and a suitable vertical jig.

2. *Penetration of Hardness, Deep Hardening Steels*—For determination of penetration on the deeper hardening steels, the $\frac{3}{8}$ in. dia. specimen employed in the P-F test cannot be used since this section would harden entirely through. The heavy sections necessary for testing these steels present considerable difficulty in cutting. Consequently the following methods using small specimens inserted in a larger block to simulate the larger mass have been suggested and used. However, they are not well established or as standardized as the method described above.

The first method consists of a disc of ordinary soft steel approximately 4 in. in dia. x $2\frac{1}{2}$ in. thick is used as the block. Four equally spaced holes are drilled longitudinally through this disc and tapered slightly so that corresponding tapered plugs of the steels to be tested can be inserted. A suggested assembly of the disc and the test specimens is shown in Fig. 37B.

After the test plugs have been driven in, the entire fixture is heated to the quenching temperature of the steels under test, and quenched. Plugs are then removed, two flat areas are ground longitudinally on opposite sides and Rockwell determinations made every $\frac{1}{2}$ in. from one end to the other. From these readings a penetration curve can be plotted as shown in Fig. 37C.

Fig. 37C—Hardness penetration curve on deep hardening steel.

disc between two cylinders of equal dia. The assembly may be held together by a bolt through the center, in which case it is necessary that one of the cylinders and

The second method for determining the penetration of deep hardening steels, and one which may be used to advantage in studying the effect of heavier mass upon the penetration characteristics of the shallow hardening steels, consists of cutting a disc of the steel to be tested measuring approximately $2\frac{1}{2}$ in. in dia. x $\frac{1}{2}$ in. thick, grinding the two surfaces of this disc exactly parallel, then clamping the

Fig. 37D—Jig for determining hardness penetration on thin disc, and for studying effect of mass.

Fig. 37E—Test piece shown in Fig. 37D after etching.

test piece be bored axially and the other cylinder tapped to accommodate this bolt. The entire assembly is then heated to the temperature desired, properly quenched and the test piece removed from the fixture. The test piece may then be etched to show penetration, or Rockwell hardnesses may be taken over the face, which will have the same characteristics with regard to hardness as if a whole bar of the same size had been quenched and cut in half. The fixture with test piece engaged, and the test piece after removing and etching are illustrated in Fig. 37D and 37E.

3. Degree of Hardening—To test the degree of hardening, the samples described under "Penetration of Hardening" may be used and the hardness read by the usual methods (See Section V—Methods of Hardness Testing).

4. Uniformity of Hardening—Soft spots are peculiar to tool steels of the shallow hardening type, due to improper quenching conditions. Misleading information will be developed if standardized methods of quenching are not employed in making a test to determine the uniformity of hardness in these steels.

A hardened sample, tool, or part, may be tested by etching the polished surface with hot 1:1 HCl or 10% HNO₃ in alcohol at room temperature. Areas of variable hardness will etch light or dark and may be explored by standard hardness testing methods.

5. Susceptibility to Hardening Cracks—A number of tool steels are susceptible to hardening cracks, due to composition, prior treatment or variables of manufacture. In determining this characteristic in steels of similar chemistry, it is important that a standardized temperature, time of heating and quenching cycle

Fig. 38—Navy specification for deformation.

be employed. To locate hardening cracks, a properly hardened sample, tool, or part may be examined magnetically as described under "Magnetic Testing," on page 770. An alternate method involves the etching of the piece in hot 1:1 HCl, 10% HNO₃ in alcohol or 10% solution of ammonium persulphate in water, at room temperature.

6. Sensitivity to Grain Growth—Difference in sensitivity to grain growth may be observed in tool steels when heated in increasing intervals above the critical. This characteristic is dependent on composition, variables of manufacture and heat treatment.

A simple test involves the hardening of test pieces (as described under "Penetration of Hardening"), over a range of ascending temperatures, starting with the normal or customary hardening temperature for a given lot of steel. For example, samples of 1.00% carbon steel are hardened at 1400, 1450, 1500, 1550, and 1600°F. in water. The pieces are fractured, compared with a standard, or examined microscopically.

7. Susceptibility to Soft Surface—A susceptibility to soft surface is peculiar to several types of tool steel. Differences between types may be determined by hardening samples of the respective lots from their normal quenching temperatures, after which accurate hardness tests may be made. In testing steels of similar chemistry, it is important to employ a standardized temperature, correct furnace atmosphere, time of heating and quenching procedure. The depth of the soft surface may be measured by a repeated cycle of uniform grinding and hardness testing.

IX—Machinability—Method for Testing for Machinability—The only practical test for machinability is one based on actual machining operations.

Machinability is not a definable property of tool steel because "machining" may involve a dozen or more different operations such as turning, tapping, reaming, drilling, broaching, threading, or backing-off. Each of these different operations is further complicated by the requirements of the job. For example, milling of the flutes in a tap might require that no burr be thrown up on the teeth, while no such requirement would be imposed on milling the flutes on a reamer. Drilling large holes does not involve the same problem as drilling small holes, and gun barrel drilling introduces still other problems. A delicate backing-off operation may dominate all other machining requirements in making certain tools.

Each user must therefore, determine the condition in the tool steel which produces best machinability for his own particular purpose. Certain tests can be decided upon, including analysis, hardness, and microstructure, which can reasonably be expected to reproduce the machinability which is desired. For any given analysis of tool steel, incoming material can be inspected for machinability by testing the hardness and microstructure and comparing them with standards which have been approved for satisfactory machinability.

X—Testing of Tool Steels for Nondeforming Qualities—All tool steels tend to distort during heat treatment. This distortion is affected by the rate of heating, rate of cooling, design of the part, and by characteristics of the steel. Obviously, in any attempt to compare steels for nondeforming qualities as affected by steel characteristics, control over all other variables must be maintained.

There should be no difficulty in maintaining uniform rates of heating for test specimens. Rates of cooling will naturally vary with the type of steel since some steels must be hardened by quenching in water or brine, others in oil, air blast, or still air. This rate of cooling, however, should be uniform when comparing different makes of steel of the same type.

The degree of hardness resulting from treatment is also important since a steel hardened to a low hardness will move less than the same steel treated to a high hardness. While uniform rates of heating and cooling should control this to some extent, a standard range of hardness for various types of steel should be used.

Numerous designs of test specimens are possible and the observer should select that standard design which most nearly meets his requirements. The following four designs are suggested:

1. Machine a section of annealed steel to $\frac{3}{4}$ in. round \times $3\frac{1}{2}$ in. long. After machining, the specimen should be given a strain relieving treatment by heating to a temperature just below the critical, followed by slow cooling. It should then be ground and accurately measured for length and diameter. A standard heat treatment should be used. The dimensions may be rechecked before and after tempering if desired.

2. A ring $2\frac{1}{4}$ in. outside dia. \times $1\frac{1}{4}$ in. inside dia. \times $\frac{3}{4}$ in. thick may be prepared and handled in the manner of specimen No. 1.

3. Flat specimens at least 6 in. square \times $1\frac{1}{2}$ in. thick are especially valuable as an indication of the movement that may occur in steels used for large dies. In this test the specimen may be prepared as described above but the measurement involves checking the face of the specimen for flatness to determine the extent to which the surface has become convex or concave.

4. Fig. 38 illustrates a specimen of nonuniform section sometimes used for movement tests. Preparation of this specimen should be similar to that suggested for test No. 1. The accuracy of this test is doubtful because of the greater effect on the movement exercised by slight changes in rates of heating and cooling.

XI—Tensile Tests at Room Temperature—The tensile properties of tool steel in the annealed condition are of little commercial value, and when tested in the hardened condition, the tensile determination presents considerable difficulty. It is possible to obtain tensile properties that do have some value by tempering to such a hardness that the steel will have appreciable reduction of area and elongation, which for many tool steels is in the vicinity of 40 Rockwell C.

When determining the tensile properties of tool steel, a specially designed test specimen is recommended (Fig. 39). In order to secure perfect alignment, special grips using the ball and socket principle are recommended.

The specimens are usually heat treated in test bar size but leaving about 0.020 in. on the diameter to permit removal of decarburized surface and correct for warpage.

XI-a—Tensile Tests of Tool Steels at Elevated Temperatures—The Joint Committee of the A.S.T.M. and the A.S.M.E. have prepared tentative standard methods* for tensile tests of steels at elevated temperatures. These methods are satisfactory for medium or low strength steels, but for high strength steels it is difficult to obtain accurate results without some modifications.

The Elevated Temperature Tensile Test Specimen—Fig. 40 shows a satisfactory form of test specimen. The best practice is to rough turn in the annealed condition; heat treat; and grind as indicated. In the case of high strength steels with low elongations, best results will be obtained if the ends are tempered for a short time in a liquid bath, previous to grinding.

The diameter of the specimen (gage length section), may be varied from the dimension shown in Fig. 40 to as small as 0.200 in. with satisfactory results. When a smaller specimen is used, the gage length should equal four diameters so that the elongation values will be directly comparable to those of the standard specimen. The detail dimensions of a small specimen are shown in Fig. 41.

Gage marks can be put on the hardened specimens conveniently with the diamond point hardness tester. Wash the surface with a copper sulphate solution where the gage marks are to be placed, then scribe the 2 in. gage length with sharp dividers and follow by prick punching or use the diamond point. If an extensometer is to be attached to the specimen, it is necessary to put gage marks on opposite sides. This procedure is much facilitated by rotating on centers and using the dividers against a rest while laying off the gage length.

The Testing Equipment—Various forms of shackles may be used to grip the ends of the specimens. A satisfactory form is shown in Fig. 42. This type is readily adapted to both the threaded-end and the shouldered-end types of specimens. The split adapters that fit the ends of the shouldered-end specimens are strengthened by the solid rings which have a tapered bore so that they can be wedged on the adapters after the specimen is inserted. Another satisfactory form for shouldered-end specimens is shown in Fig. 42a.

The best furnace for making high temperature tensile tests is a differentially

*See A.S.T.M. Proc., 1934, v. 34, pt. I, p. 1214 (E21-34T and E22-34T).

or gap wound resistance type of electric furnace with particular attention given to baffling, insulation, and tightness so as to prevent temperature gradients either in the specimen or the adjoining shackles. For short time, elevated temperature tensile tests manual control of the temperature is generally adequate, but for the long time or creep tests automatic control becomes mandatory. In any case, it is essential to know the actual temperature of the specimen and maintain this temperature throughout the reduced portion at each temperature used.

Fig. 39

Fig. 40

Fig. 41

Fig. 39—Special tensile test specimen for tool steel. The ends may be square or ball-shaped. Fig. 40—Tensile test specimen for tool steel at elevated temperature. Fig. 41—Same as Fig. 40, but where a small specimen is required.

The use of the extensometer in high temperature work makes the maintenance of uniform temperatures so difficult that the best results are often obtained by compromises between heating equipment and deformation measuring apparatus. The use of the smaller sizes of specimens assist in obtaining uniform temperatures throughout the specimen.

Self-aligning shackles are quite essential. The usual method is to provide ball and socket joints at the ends of the shackles where they are attached to the heads of the testing machine as indicated in Fig. 42.

Testing Procedure—It is particularly important in short time high temperature tensile tests to heat slowly for consistent results. Many of the published discrepancies are due to too fast a heating rate. The elastic properties of tool steels as usually determined, such as elastic limit, proportional limit, and frequently Young's modulus, are of questionable value because of creep phenomena at the higher temperatures and the difficulties contingent upon their determination. Better results will be obtained by the use of yield strength values based on some arbitrary permanent set, or perhaps two different permanent set values such as 0.1% and 0.2%, following the methods given in the standards of the A.S.T.M. (E8-33). Such yield strength values need be used only in the absence of a well defined yield point in the steel, but most tool steels have no well defined yield points.

Temperatures are best obtained by clamping thermocouples directly on the shoulders adjacent to the gage length of the specimen. Shield the hot junctions from heat of the furnace walls by placing asbestos paper over the junctions before applying the clamps. Additional thermocouples in the furnace atmosphere and shackles may assist in obtaining and controlling the desired temperatures, but generally are not reliable for measuring specimen temperatures.

In reporting results, the details of the specimen apparatus and procedure should be given in addition to the composition and history of the material.

XI-b—Tool Steel—Compression Testing—The object, generally, of compression testing is to determine stress and deformation under load, and the load necessary to produce failure.

Fig. 42 and 42a—Types of shackles used to grip ends of tensile specimen.

For tool steel, the latter information is all that is usually required. The test is used mostly in connection with problems of tool design, or in comparison of one type of steel with another, or one heat treatment with another. The material is tested in the hardened condition.

Fig. 43 and 44 show types of specimens which have been used. The form shown

by Fig. 44 is usually preferred. The method of carrying out the test is illustrated by Fig. 45. The following precautions are essential:

1. One bearing block must be provided with a spherical seat.
2. The specimen and bearing blocks must be accurately centered on the table of the machine so that the line of pressure will pass through the axis of the specimen, bearing blocks, and testing machine.
3. Apply the load at a uniform rate, generally less than 0.02 in. per min.
4. Full protection from flying pieces must be provided.

The drop of the beam or dial pointer is usually taken to indicate ultimate failure. It is recommended that the test be stopped at this point. The load at rupture may be somewhat higher, but is considered to be without significance due to the radical change in shape and dimensions of the test piece. For more complete particulars, see references 1, 2, and 3.

For measuring the resistance of a superficially hardened object to local crushing or sinking under load, two methods have been used. The first makes use of a plain cylindrical hob which is pressed into the object to be tested, using suitable increments of load. After each increase of load has been applied, the hob is removed and the piece examined. The load at which the first signs of permanent sinking occur, is taken as an indication of the local carrying capacity of the surface. In the second method, described by O. W. McMullan¹ special Brinell balls, preferably of the hard carbide variety are pressed into the surface to be tested under increments of load, the impressions being measured in the usual manner.

XII—Impact Tests—The standard impact tests as described on page 50 are not commercial tests for tool steel, as the values obtained mean little in the annealed condition and when testing is done in the hardened condition, the values are too erratic.

When this type of testing is used the design of the test bar may be varied according to the characteristics of the steel.

The test bars are highly stressed and care is necessary to prevent injury from the flying fragments during the impact testing.

The torsion impact test is comparatively new for developing information on tool steel harder than Rockwell C 60. The full significance of the test and its results must await further developments.

XIII—Torsion Test as Applied to Tool Steels—The problem of determining accurately some of the fundamental properties of hardened tool steel is difficult in that exceptionally high strengths and low degrees of toughness as compared to the engineering steels, are encountered. The tensile transverse bending, and impact tests have limited usefulness when applied to hardened tool steels as results are apt to vary and the average is only approximate. The static torsion test has the advantage over the above in that the applied stress is not so much concentrated

and it is possible to measure much more accurately both strength and toughness even when the latter is very low. With this method of testing, simultaneous observations of both stress and strain are made, and from these results curves can be plotted showing both the elastic and plastic deformation and the approximate location of the yield point.

Fig. 44

Fig. 43 and 44—Compression test specimens for tool steel. With both specimens trim "D" to about 0.020 in. oversize. After hardening grind "D" to 0.505 ± 0.0005 in. Grind both ends square and parallel with no centers. Use special care in finishing the radii in Fig. 44.

The angle through which the specimen twists is recorded for each increment of 25 in. lb. torque until rupture occurs. From these data a stress-strain curve can be plotted which gives information as to the elasticity, plasticity, and ultimate torsional strength of the material being tested.

XIV—Cutting Tests—See the work of F. W. Taylor, "On the Art of Cutting Metals," Trans., A.S.M.E., 1907, v. 28.

XV—Fatigue Testing of Tool Steel—The ordinary fatigue tests used on soft or medium hard materials may be, but seldom are, applied to annealed tool steels, since tool steels are largely used only in the hardened condition. These tests are not generally used on hardened tool steels because the variations in results due to notches, scratches, and residual strains overshadow those caused by differences in steel quality. Their best application on tool steels would be on specimens that have been hardened and then tempered to comparative softness—a treatment seldom used for tools.

Fatigue tests of tool steel indicate an endurance limit of from $\frac{1}{4}$ to $\frac{3}{4}$ of the static tensile strength, and show that the fatigue resistance is materially increased by changing the direction of final polish of specimen from circumferential to longitudinal.

The main emphasis in dealing with fatigue problems in tool steels should be laid on the design and treatment.

Some manufacturers and users of hollow mining drill steel have long used a practical fatigue test to check the quality of various lots of this material. This test with modifications may be applied to other types of pneumatic tools. It consists of running a representative number of test bars of definite size and length in a jack hammer until failure occurs from fatigue. The time required is compared with standards agreed upon by manufacturer and consumer.

XVI—Damping Capacity—Damping capacity is that property of engineering materials and particularly of metals which enables them to dissipate energy without failure when subjected to cyclic stresses below the fatigue limit. This property is also known as "mechanical hysteresis effect," "dynamic ductility," and "internal friction" of solids. The damping capacity of a material is the amount of work dissipated into heat by a unit volume of the material during a completely reversed cycle of unit stress, and is measured in in.lb. per cu.in. per cycle. To study this ability of metals to dissipate energy when stressed well below the elastic limit by the method of measuring the areas of "hysteresis" loops demands extremely delicate apparatus and test methods. The method generally employed is that of measuring

Method of Making Torsion Test—Owing to the high strength and low toughness of hardened tool steels, a test specimen with a comparatively high ratio of "L" to "D" is necessary for best results; (L = length of gage section, D = outside diameter of gage section). Where a ratio of 5.78 is used for relatively soft materials, a ratio of 16 is recommended for hardened tool steels so that sufficiently large strain values can be obtained for a given stress. A drawing of the torsion test specimen for tool steels, picture of the torsion testing apparatus, and details regarding the method are given on pages 47 and 49, A.S.T.M., Proc., 1931, v. 31, pt. 2.

The principle of the test is that by means of a manually operated turning head, a twisting torque is applied to the torsion specimen which in turn transmits the torque through a lever system and hydraulic gage to a piston. The gage reading indicates the applied twisting force or torque in in. lb., and deformation or angle of twist is directly measured on the twisting head of the machine.

the cumulative effect of such hysteresis loops by observing the rate of damping out of vibrations in specimens of the metal. A simplified type of apparatus is shown in Fig. 46.

A specimen S , usually round and solid, is twisted slightly by the action of two magnets M_1 and M_2 . When the current in the magnets is broken, the specimen vibrates back and forth and a record of its vibrations is made on a paper P , which is moved by clockwork. An ideal "damping" machine would be one which permitted damping of a freely vibrating specimen only by internal friction in the specimen.

Although it seems proper to co-ordinate higher damping capacity with smaller tensile or hardness values, at least so far as steels are concerned, many experiments have shown that the damping capacity may be quite different for steels of identical chemical and tensile properties. A material of high damping capacity is less sensitive to the influence of surface notches or sudden changes in cross section than one of lower damping capacity.

Duralumin has an extremely small damping value; on the other hand, cast iron has a surprisingly high damping capacity.

Fig. 45

Fig. 46

Fig. 45—Method of making compression test. Fig. 46—Apparatus for damping test.

XVII—Magnetic Testing—See page 770 for an article on Magnetic Testing.

XVIII—X-Ray Test—Radiography—Defects occurring in tool steels are usually of such a nature that they are not readily revealed by the X-ray.

Diffraction Methods—Diffraction or crystal structure analysis has been used for fundamental studies of the components of tool steels but no routine inspection has been established.

XIX—Determination of Critical Points—There are three methods of determining critical points of tool steels: (1) One is by plotting the heating and cooling

curves on time-temperature co-ordinates (Fig. 47); or (2) by dilatometric measurements involving the charting of interruption of progressive expansion or contraction on linear expansion temperature coordinates; or (3) by plotting the change or loss of ferromagnetic characteristics on a temperature magnetic intensity diagram.

1. Thermal Critical Point—In ordinary practice, critical points are critical ranges, since a small temperature range is required to complete the change in physical and physicochemical characteristics.

The method of inserting a thermocouple into the drilled test sample and observing and recording the rate of rise or rate of drop of temperature on time-temperature diagram is probably the oldest and most simple method of obtaining the critical points.

A heating and cooling rate of from 1-2°F. per min. is used to determine with fair accuracy, the transformation points. Its accuracy, of course, depends largely upon the quality of furnace equipment. To eliminate this factor, a neutral or nontransforming metal such as platinum, austenitic nickel steel, or austenitic alloy steel is heated along with the sample and temperature differences of the two observed. The inverse rate of heating and cooling curves, shown in Fig. 47, give sharp peaks on the curves which correspond to the amount of heat absorbed on heating or the heat evolved on cooling. The inverse rate curves are in general use. Autographic recorders are very desirable and where frequent determinations are required, they are indispensable.

Dilatometric Method—The dilatometer is essentially a mechanism for determining the expansion or contraction of a sample with changes in temperature.

Magnetic Method—The magnetic determination of critical points depends upon the loss of ferromagnetic properties and by observing the magnetic transformation and the corresponding temperature these points are established. The tool steel sample is inserted as an armature in a magnetic circuit and when the tempera-

ture is reached at which magnetic flux ceases to pass through the steel sample or when it disrupts the circuit, the loss of ferromagnetism indicates the critical point. A galvanometer connected into the line will drop to zero position and may be made to record this loss on the temperature curve.

XX—Abrasion Tests—Abrasion testing consists of measuring the loss of weight of the unit surface area of a sample of tool steel, after moving over and in contact with a standard hardened and finished machined surface, for a definite number of strokes and under a definite pressure, representing, as far as practical, service conditions.

Fig. 47—Different types of critical point curves. "A" inverse rate heating and cooling curve for a 0.45% carbon steel, and "B" the same for a 1.00% carbon steel. "C" smear expansion of a 0.45% carbon steel as determined on a dilatometer.

This loss per unit area of the tool steel sample compared with the loss per unit area of other samples of different physicochemical composition, but of identical surface dimensions and tested in this same manner, gives the abrasion value expressed in loss of weight units per unit surface.

The surfaces may be cylindrical, spherical, or flat, but whether they are curved or straight, maximum and uniform contact and proper machine or mechanical finishes are essential.

See the A.S.T. Trans., v. 10, p. 692, French and Herschman, Wear of Steel, with Particular Reference to Plug Gages, for illustration of wear testing machine for cylindrical surfaces.

Acknowledgments—The Subcommittee on Tool Steel wishes to acknowledge and thank the following individuals for the valuable assistance which they gave the committee in the preparation of this report: Oscar Harder, Henry Keshian, Kent R. Van Horn, Vincent Malcolm, F. H. Allison, Jr., C. W. Schuck, O. W. Boston, R. L. Templin, B. H. DeLong, J. V. Emmons, H. F. Moore, H. T. Morton, and R. G. Kennedy, Jr.

Notched Bar Testing of Steel*

Good practice in the design and manufacture of steel parts avoids, wherever feasible, the occurrence of notches and sharp changes in cross section, while sound metallurgical practice seeks likewise to avoid the presence of coarse slag inclusions, internal cracks, and other defects which are likely to simulate external notches. The action of such notches is to concentrate the stresses resulting from applied loads, and when the notch is sufficiently sharp, a crack is produced, the propagation of which causes failure of the part. These failures are of the brittle type, characterized by complete cleavage through the notch, though the metal may be ductile when not subjected to the stress conditions of a notch. Steel parts differ in their susceptibility to a notch effect and this difference is frequently not indicated by any of the tests carried out on unnotched specimens. This article discusses notch behavior and gives a test procedure for use with steel.

Because the conditions encountered in service are frequently complex, and the precise state of stress unknown, it is not to be expected that it will always be possible to correlate service failures which are due to a notch or to notch brittleness, with tests on notched bars carried out in the laboratory. However, by recognizing the principles of notch behavior, it should be possible to establish a notched bar test that will serve as a guide to the selection of a metal (and its treatment) of sufficiently low notch sensitivity when that is required. It must be borne in mind that it has not been demonstrated that there is any connection between notch sensitivity as measured in a test involving a continuous application of load and notch sensitivity as measured in tests in which the load pulsates as in notch fatigue testing. The broad principle upon which a notched bar test should be planned and interpreted is as follows: All steels break in the brittle manner under a notch of sufficient severity, but the severity of the notch required to cause brittle failure may vary somewhat among steels which have the required strength and ductility and it must be independently determined; furthermore in this test steels may also vary in the temperature below which failure will be brittle for a notch of a particular degree of severity.

Distinction Between Notched Bar Testing and Impact Testing—The notched bar test distinguishes between conditions of steel which are more or less sensitive to a notch while an impact test distinguishes between conditions of steel which are more or less sensitive to the speed at which the metal is deformed. Notch sensitivity and velocity sensitivity are two different and distinguishable characteristics and should be studied by different test techniques. Due largely to the circumstance that the energy to fracture the notched test bar is determined on an impact machine, the test is commonly called an "impact" test and considerable misunderstanding has arisen as to its correct nature. More often than not, it is regarded as a test of behavior under impact and hence it seems desirable here to point out that the stress conditions imposed by a notch and the stress conditions imposed by an impact belong in entirely different categories. Notch sensitivity of a steel can be detected and studied by methods which use purely static loading. A bad effect of this misunderstanding is that the attempt is improperly made to correlate the energy absorption of the notched bar test (the impact value) with behavior in service which involves merely impact or "shock" with no notch present. The true correlation is with service behavior which involves the stress conditions of the notch effect. In some cases, which are not well understood at present, it is recognized that a notch brittle condition is observed in impact or at one speed of loading but not at a lower velocity. Obviously these are cases of "velocity sensitivity" and they ought not be overlooked in practice.

Theory of the Notched Bar Test—The Ludwik theory of the notch effect¹ shows that brittle failure of ductile steel is produced when the cohesive strength is exceeded before deformation sets in. The cohesive strength is defined as the strength property of the metal that resists the tensile, disruptive stress across a plane at right angles to the applied load. In the tensile test the steel is ductile because the elastic limit in shear is low enough to permit flow by slip before the cohesive strength is exceeded. As long as the cohesive strength is at least at this level with respect to the elastic limit in shear there is nothing in the tensile test to indicate whether it is high or low, relative to the cohesive strength and shear yield that is usually expected for

*Prepared by the Subcommittee on Notched Bar Testing. The membership of the subcommittee was as follows: S. L. Hoyt, Chairman; E. C. Bain, M. Gensamer, G. C. Riegel, R. Sergeson, and G. H. Wright.

that steel. The presence of a notch alters the relation between the normal stresses, which tend to part the metal by brittle fracture at 90° to the direction of the stress, and the shear stresses, which tend to make the metal deform by slip along planes at 45° . As a result of a large number of studies of the effect of a notch on the stress conditions it is known that the ratio of normal stress to shear stress is greatly increased. There is also a marked concentration of the normal stress at the root of the notch which is particularly pronounced when a bending moment is applied. In this way the normal stress may rise above the cohesive strength and produce a brittle fracture before the shear component is high enough to produce plastic deformation.

In notched bar testing we are usually concerned with the notch toughness of a steel which meets certain requirements for strength and ductility in the tensile test.

Fig. 1

Fig. 1—Effect of width of bar on the impact value. Height of all bars was 30 mm. (Moser).

Here the resistance to plastic deformation is fixed at the level of the yield point, converted into the shear stress at 45° to the axis. The cohesive strength is not determined directly but an idea of its level can be obtained if we know the intensity of the notch effect required to produce brittle failure. The principle is illustrated by Fig. 1 taken from the work of Moser.² As the width of the test bar is increased, with the notch remaining the same in all bars, the intensity of the notch effect increases. In the case of the steel specimens used in the illustration a width of 2.5 cm. was required to produce brittle fracture. Other steels of the same tensile properties might require a narrower or a wider bar for brittle fracture and they would be less or more notch tough respectively than the steel represented.

Cohesive failure with little deformation requires but little energy and hence in the notched bar test a small impact value is recorded for notch brittle steels. The Ludwik theory makes it clear that the ordinary tensile test,

or even an impact test on a plain bar, cannot be used as a substitute test for notch sensitivity.

Present Testing Practice—At present a "standard" notched bar is broken by a single blow on a pendulum type impact machine, at the ordinary laboratory temperature or at some specified temperature, and the energy required to break the bar is determined in foot pounds. This impact value is used as a determination of the "notch toughness" of the material, though good practice requires this to be judged according to what has been proven to be acceptable or not acceptable for the material in question, and its application. It may be pointed out here that a single test shows only that the specimen broke in a tough or in a brittle manner when tested under the specific test conditions used, but does not reveal what the behavior would have been had other test conditions been used. These points will be dealt with again under the proposed procedure.

Impact Testing Machine—Two types of impact machines are commonly used, the Charpy and the Izod, both of which employ the swinging pendulum. Instrument manufacturers have modified certain details of these machines, but the principles of all will be made sufficiently clear from the following description. Either type of notched bar can be used with either machine, though, as will be made clear directly, the length of the bar and position of the notch are different for these two machines. The Charpy machine has a total available striking energy of 30 meter-kilograms (217 ft. lb.). The bar is supported at both ends as it lies in position on the split anvil and is broken by a blow opposite the notch. The distance between supports is 40 mm. or 1.575 in. The Izod machine breaks the bar by a blow at the end as the bar is held rigidly in a vise. The notch comes just outside the jaws. In both

cases the test bar is broken by a single blow and after breaking the bar, the pendulum swings past the anvil and rises to a height which depends on the amount of energy which was extracted by breaking the bar. In other words the work which is done in breaking the test bar takes that amount of energy out of the moving pendulum with the result that it does not rise to the height it would if swinging freely. Hence the energy to break the bar is given by the effective weight of the pendulum times the height of fall minus the height of rise, with a small correction for friction and windage. A scale with moving pointer gives the reading of the "impact value." This may be either in foot pounds direct, or in the angle of rise which is converted into foot pounds. At times only one bar is broken though it is better to use two or more to secure a check.

The Charpy test is commonly used in continental Europe, and the Izod test is used in England. Although this country has not attempted to select a standard notched bar test, and both the machines and both of the notches are used, the advantages of the Charpy notch and the absence of a vise for holding the specimen make the Charpy test appear preferable for a standard. On the other hand the Izod may be better suited to testing rounds and miscellaneous shapes.

Type of Specimen*—In this country two test bars are used, one the Charpy bar of Fig. 2 and the other the Izod bar of Fig. 3. The Charpy bar should be either 2 in. long or 2.165 in. long, depending on the testing machine. The main difference between these bars is in the notch. The Charpy notch is of the key hole type with a radius of 1 mm. (.0394 in.) and a depth of 5 mm. (.197 in.). The Izod notch is also used for test bars which are broken on the Charpy machine. A record of the impact values of notched bars should be accompanied by a statement covering the notch which was used. On account of the difference in the design and depth of the notch, test results with these two bars cannot be directly related though it is possible to secure a calibration of one in terms of the other. In general if a specimen is tough, the Izod value will be above the Charpy value because a greater cross section is broken, while if the steel is critically notch brittle the Izod value will be lower because the V notch gives a more severe notch effect.

Fig. 2—Charpy notched impact specimen.

Fig. 3—Izod notched impact specimen.

Fig. 4—Proposed test bar of intensified notch effect which is the same as Fig. 2 except for double the width.

ing, or grinding but care should be exercised to avoid enlarging the hole or cutting into the side of the drilled hole. The latter can be avoided by placing a copper wire in the hole while making the saw cut. Test bars which are to be broken in a hardened condition require a special technique. The hole cannot be drilled but, with

The notch of Fig. 2 is preferred by many on account of the ease of making it and particularly on account of the precision with which it can be reproduced. The hole is drilled with a No. 47 drill which, with a diameter of 0.0785 in., is close to the Charpy standard of 2 mm. or 0.0788 in. By placing the bar in a fixture this hole can be drilled tangent to the center line so that the depth of section to be broken can be held to just 5 mm. or 0.197 in. The drilling operation leaves the scratches running around the hole, or in the most favorable direction to avoid low results arising from them. For greater reproducibility the hole can be carefully reamed out but that is seldom considered necessary. If the steel is too hard for drilling (about 400 Brinell or 40 Rockwell C hardness numbers) the notch can be made by grinding. After the hole is drilled, a slot is opened up to the surface by sawing, mill-

*Attention is directed to the A.S.T.M. specification of a sharp V notch for the test bar which is broken on the Charpy machine, as is given on page 135.

suitable precautions, can be ground to dimension. It is also feasible to drill the hole before hardening and to insert a soft steel wire which will completely fill out the hole, and then to heat treat the test bar. This hole is subsequently opened up to the surface.

The Izod notch is used by some because it gives a larger numerical spread between notch tough and notch brittle materials than is obtained with the more generous radius of the Charpy notch. On the other hand the radius of the Izod notch is so sharp that reproducibility is sacrificed unless great care is exercised in its production. Furthermore, the Izod notch is so shallow that the volume of deformed metal may extend out to the outer face of the test bar. When this occurs, the full notch effect is not developed and the use of the impact value as a measure of the notch toughness is vitiated.

Precautions Necessary for Reproducibility of Results—Two features of great importance are the method of making the notch, and placing the bottom of the notch tangent to the center line of the bar. The other dimensions should be held as shown. The accuracy which is usually maintained is ± 0.001 in. though if it will lower the cost of preparing test bars this can be increased to ± 0.003 in. on harder steels and to ± 0.005 in. on softer steels without endangering the reliability of the results. The jig which is used in drilling the hole may require the more accurate finish.

The impact machine should be known to conform to standard requirements, and to be of correct calibration. Frictional losses can be checked from time to time by permitting the pendulum to fall freely and noting the decrease in the oscillations. The small fixture which is used to place the test bar at the correct position on the anvil can also be used to check the zero position of the pendulum. The test bar should be accurately placed on the anvil so that the tip of the pendulum will strike it at a point opposite the notch. This placement can be properly made with the aid of a template. Furthermore, the anvil should be so designed that the test bar clears the sides of the anvil with no undue loss of energy from scraping.

The effect of variation of temperature in notched bar testing is extraordinarily great. The laboratory temperature may vary as much as 30°F . between summer and winter and with some steels this is sufficient to affect the impact values materially. To obtain reproducible results in some cases requires holding the temperature of the test bar to a range which does not exceed 10°F . The effect of temperature will be commented on at greater length in a later section.

Other factors which affect the consistency of the results are associated with taking the sample and conditions of heat treatment. Forgings and rolled sections have definite flow lines or fibre, while nonmetallic inclusions are also drawn out in directions parallel to the direction of metal flow. If the length of the test bar is parallel to the direction of the fibre the impact value is higher, at times by as much as twofold, than it is if perpendicular to that direction. Furthermore, the direction of the notch in the test bar may likewise have an effect on the impact value. Heat treatment frequently alters the surface. Usually this change is a decarburization, which usually acts to increase the impact value, though it may be a carburization which acts to lower the impact value. The discussion of such factors could be elaborated, but it is sufficient to say that in each case the test bar should be made by a procedure which insures having the metal in the desired condition. As a precautionary measure, at least 0.025 in. can be left on all faces for final machining and grinding, and the notch can be made last.

Inasmuch as most notched bar testing is done on impact machines, the velocities of which do not vary materially, the effect of velocity on the reproducibility of the results is not often significant. Considerable work has shown that with most steels, about the same energy absorption is secured whether the bar is broken statically, or by impact at normal speed. On the other hand it has also been shown that some steels are velocity sensitive and when broken statically they remain tough in wider sections or with sharper notches and at lower temperatures than when broken by an impact. This field of velocity sensitivity requires more study than has been put on it before an adequate discussion can be given.

Proposed Procedure for Notched Bar Testing—Present practice is correct for determining the impact value of a specimen under the specified conditions of the test used but is not capable of giving a complete understanding of the notch behavior or notch toughness of that steel even for a single condition of treatment. In brief when we test a steel with a specific notch, at normal laboratory temperature, and at the speed of a standard testing machine, we learn whether or not those condi-

tions are severe enough to develop brittle behavior in the specimens tested. If we know that the notch used is just sufficiently severe for the particular application to be made, the test is adequate. This is particularly true in view of the improvement in the uniformity of steel making and steel treating practice of recent years. On the other hand, the conditions of service may be of such a nature that the standard test no longer suffices; the notch used may be too severe or not sufficiently severe. This must be ascertained by experience. The following is given as a guide to correct laboratory procedure, when the application involves notches more severe than that of the standard test or when a more searching test is desired. This involves the use of variables which alter the notch effect of the notch used, the temperature of the test bar, and the striking velocity.

It has been shown that a notch of a given sharpness and depth has a greater effect on the ratio of the maximum normal stress to the maximum shear stress, if the width of the bar is increased. The proposed test bar of intensified notch effect is shown in Fig. 4 which is double the standard width but otherwise the same as the standard bar. The energy required to fracture is obtained as before and compared with the value for the standard bar. The selection of this width is arbitrary but experience has shown that it is satisfactory. Breaking the double width bar gives valuable information on the quality of the steel. Ordinarily it gives about double the single width value but may fall well below this and even below the value of the standard bar. Depending on the single and double width values, the steel is accepted or rejected, or diverted from the use originally intended to one which is less critical. In about the same way bars of triple width may be broken and the impact values compared with those of the single and double width bars. The desirability, or necessity, of so extending the test is to be determined for the individual application. Somewhat the same judgment could be secured by comparing the Charpy notch with the sharper Izod notch. If the steel is sufficiently notch tough, the greater area of the Izod bar will give greater impact values; but if the steel is notch sensitive, its more intense notch effect will give a lower impact value. The double width bar is more convenient, for use can be made of the simple mathematical relationship between the double width value and twice the single width value to judge the steel. Single and double width bars with the Izod notch (or other V notch) can also be used in special cases.

A second condition that requires an extension or modification of the standard test is that imposed by service temperatures which lie below the ordinary laboratory temperature. The strength and ductility of steel in the tension and torsion tests vary but little over the range of atmospheric temperatures. A test for those properties can rationally be made at room temperature though the operating temperature be lower. Notched behavior comes in quite a different category. A steel which is relatively insensitive to a certain notch at room temperature can be quite notch brittle at a lower temperature. In many cases this change in behavior can be brought about by lowering the temperature to the freezing point (32°F.). If a different notch is used, the temperature at which notch brittle behavior is produced will be higher as the severity of the notch effect increases. Obviously it may be necessary on some occasions and desirable on others to test steel at some temperature below room temperature. Such a procedure has already been incorporated into testing inasmuch as acceptance of steels for low temperature service is based on notched bar tests at temperatures ranging from -58°F. down. It is proposed that this factor be more fully taken into account and that test temperatures be utilized, when the occasion warrants, which lie below room temperature. This amounts to a recognition of the rapid change in notch toughness that can occur over this particular temperature range.

When carrying out subnormal tests the test bars should be held at the temperature in question for at least 30 min. or until equalized, and then broken quickly. These temperatures can be readily enough obtained in the laboratory by using tap water, chilled water, melting ice, and freezing mixtures. In the case of temperatures which lie well below normal, the test temperature is secured by means of dry ice plus acetone, or even with liquid air.

"Velocity sensitivity" of steel when tested by a notched bar test has already been mentioned. A complete procedure should include a test of this factor whenever it is an important component of the service conditions. A promising method of attack is that of determining the static stress-strain diagram of the notched bar and comparing the energy value with the impact value as ordinarily determined. The static diagram further characterizes the steel by distinguishing between strong steels and ductile steels, both of which may have the same impact value. It may

also be used to determine the amount of energy absorbed up to the point of failure by crack formation. That value appears to be a more significant criterion than the total energy of rupture.

Interpretation of Test Results—The interpretation of notched bar test results necessarily involves certain strict limitations. First of all the test is pertinent only to such applications as involve the effect of notches to reduce the manifestation of plasticity in the material. At times it will be employed to verify the degree of the sensitivity of a steel composition or of a heat of steel to the notch effect, or to ascertain the effect of a thermal or a mechanical treatment. In any comparison of this kind the specimens of the material in question must be comparable in the other essential characteristics with those specimens which serve as a criterion. Thus, for example, they should, depending upon use, have the same ultimate strength or the same yield strength or the same tensile ductility or the same hardness (a difference in the tempering temperature which would make even two or three points difference in Rockwell C hardness may greatly alter the results of the notched bar test even in specimens from the same bar).

Furthermore the grain size established in the material in question should not be coarsened by an unsuitable heating temperature in hardening for this alters the notch response of any steel tremendously. Internal stress is particularly potent in determining notch sensitivity of a specimen and care should be taken, in quenching and tempering technique, for example, not to vitiate the comparison by a disparity in this respect which in good commercial practice would not exist.

Table I

The proportional limits, yield points, tensile strengths, fatigue strengths, and notch fatigue strengths are in psi. The elongations and reductions in area are in per cent. S.W. = single width bar, and D.W. = double width bar.

Comments on Table I

Items 1 and 2 give a comparison of two steels of closely similar tensile properties.

Item 2 is deficient in impact value, particularly at double width.

Items 3 and 4 compare two carbon steel forgings of different heat treatment. Item 3 is seen to be deficient in the double width impact value though it is otherwise of good properties.

Items 5 and 6 illustrate the effect of heat treatment on a carbon steel forging. The double width bar brings out the better condition of Item 6.

Items 7 and 8 show two different conditions of a forging, with satisfactory and unsatisfactory impact values.

Items 9, 10, 11, 12 and 13 give typical properties of several S.A.E. steels. Items 9 and 10 represent $\frac{1}{2}$ in. round bars water quenched and tempered as shown. Items 11 and 12 represent .520 in. round bars oil quenched and tempered as shown.

It will be clear from what has been said that the simple test may be quite inadequate. This situation places great emphasis on the test conditions which are used in notched bar testing. It also reflects the technological nature of this test, for it does not measure a property but simply reveals the behavior of the steel under certain specific conditions.

While this article deals with testing procedure rather than with test results it may clarify matters by citing an illustrative case. A medium carbon steel forging was given two different heat treatments and tested after each one. In both cases the standard Charpy bar with key hole notch gave 15 ft-lb. Undoubtedly either heat treatment would be suitable for many applications. The testing procedure which is advocated here showed one of them to be inadequate for more exacting service. When the double width bars were also broken it was learned that with one heat treatment a value of 30 ft-lb. was obtained, and with the other only 7 ft-lb. Incidentally, the steel in the latter condition was found to be softer and more ductile in the tensile test. For more exacting service, or if a good factor of safety is desired, it is clear that the steel cannot be judged adequately on the basis of the standard test alone. On the other hand, if only double width bars are used, some material may be rejected though it be suitable for less severe service.

As a guide to normal impact values which may be expected for a number of typical cases the data of Table I are given.

Inspecting and Testing of Bolts, Screws, Nuts, Studs, and Pins*

General—The inspecting and testing of parts having threaded sections such as bolts and screws may include one or more of the tests covered in this article, which are as follows:

Chemical Analysis	Elongation
Mechanical Inspection (Dimensions)	Reduction of Area
Inspection of Finish and Appearance	Head Test
Hardness	Bend Test
1. Brinell	Shank Fracture Test
2. Rockwell	Impact Test
3. Scleroscope	Torsion Test
4. File	Shear Test
Tensile Test	Thread Stripping Test
Elastic Limit	Macrostructure
Yield Point	Microstructure
	Inspection of Coatings

Appearance and Finish—These products should be free from harmful defects such as burrs, laps, excessive scale, rough tool marks, dirty threads, rust, and visible raw material defects. The application to be made of any item usually determines what may be considered as harmful.

Sampling—When a shipment is made up of a number of containers such as kegs or boxes it is suggested that, for testing, one or more samples should be taken from each container, thus representing as nearly as possible the average quality of the shipment.

Mechanical Inspection—The physical dimensions are determined by suitable rules, gages, micrometers, and special instruments. Thread dimensions and tolerances for the several classes of threaded products are specified in the report of the National Screw Thread Commission and are accepted as standard.

An essential part of mechanical inspection is the frequent checking of the routine testing instruments against master gages.

Chemical Analysis—The important elements are determined by the well established methods for chemical analysis and from representative samples taken from the entire cross section of the part.

Hardness Determinations

Brinell Hardness Testing—The Brinell hardness test is generally used when the size, shape, and character of the section permit. When possible, the Brinell hardness determination on headed sections should be made near the center on the top of the head. The sample pieces may be slightly but smoothly ground when it is necessary to remove scale, decarburization, or surface roughness. See the article on Brinell Hardness in this Handbook for details of preparing the specimen and making the test.

Scleroscope Hardness Testing—The Scleroscope test may be used where the indentation resulting from the Brinell or Rockwell test would be objectionable because of impaired surface finish or serviceability. See article in this Handbook for details on the method.

Rockwell Hardness—The Rockwell C scale is used on hard surfaces and the B scale on soft surfaces where size, shape, or application of materials will not permit the use of the Brinell. See the Rockwell Hardness article in this Handbook for details of the method.

Monotron—For case hardened parts the monotron may be used. For details see the article in this Handbook on this method of testing.

File Hardness—Although its use is not standardized, the file is often used as a guide in estimating the hardness and uniformity of surface hardened parts, especially where resistance to abrasion is of major importance.

Tensile Tests—A threaded section may be considered as a cylinder strengthened by one or more spiral ridges which are the threads of the screw.

*This article was prepared by the Subcommittee on Bolts, Screws, and Nuts. The membership of the subcommittee was as follows: H. B. Pulsifer, Chairman; C. L. Harvey, and C. E. Zwahl.

The strengthening effect of the threads is usually greater on the yield point and elastic limit than on the tensile strength and is usually greater for coarse than for fine threads.

An excellent method for writing specifications is to state the minimum load in pounds for the yield point or tensile strength that a given specific part should sustain. This must be appreciably lower than the expected mean loads because of the distribution of results (see section headed *Distribution of Results*).

With bolts that are roll threaded but not heat treated the strengthening effect is greater than for either fine or coarse cut threads. The greatest strengthening effect is after a cold extrusion of the size of the pieces in the section to be threaded followed by roll threading. Materials that harden rapidly on cold working (stainless irons) also have large increases in strength after roll threading. In the extreme case, the strengthening effect of the threads may be the equivalent to an area increase of the full cross section of the piece.

It is recommended that the mean diameter¹ be used as the basis for calculating the area of threaded sections. This is done in spite of the fact that the area based on root diameter is in common practice at the present time.

The tensile properties of unthreaded sections are calculated on the minimum cross sectional area. If when testing a threaded section, the part breaks outside of the threaded section, the area of the section that breaks should be used for the calculation.

Tensile tests should always be made in special self-aligning grips. On threaded sections, tension is applied between the head and a nut screwed onto the threaded end, or special split threaded grips. Since a straight section turned out of a threaded piece may give a result far from the properties of the piece when pulled as a threaded section, it is recommended that the actual piece should be tested whenever possible.

True Elastic Limit—The elastic limit is determined in the tensile machine and is denoted by the number of pounds required to produce permanent deformation, which is determined by dividers, extensometers, or by means of an autographic attachment. The value is expressed in terms of pounds per square inch. On the threaded sections, the value is figured on the mean area.

Yield Point—The yield point is usually determined by the "drop of the beam" on the screw type machine or by the action of the pointer on the hydraulic machine.

Tensile Strength—The tensile strength, determined in the tensile machine, is the maximum load in pounds required to break the specimen and is expressed in pounds per square inch, figured on the mean area.

Elongation—The elongation of a threaded section is measured after the tensile test and is usually expressed as the percentage increase in length of a measured section (usually 2 in.). If the entire elongation is in a short length (less than 2 in.) of the threads, it is only necessary to divide the total elongation, expressed in fractions of an inch, by 2, to get the percentage elongation in 2 in.

Reduction of Area—The reduction of area is seldom determined on threaded sections. This determination is desirable, however, when testing a standard test specimen because the reduction of area and the elongation are indicative of the toughness and ductility of the metal.

Head Test—To determine if there is proper union between the head and shank, samples may be tested by placing the bolt sideways on a block of steel with its head just over and against the square edge. The head is then hammered vigorously to determine if the steel deforms plastically or ruptures.

Bend Test—Although it is not standardized, the bend test is often used on the shank of bolts as an aid in judging the toughness and ductility.

The bend test is best made in the tensile machine with a specially designed fixture which contains a series of mandrels of various sizes, thus permitting the bolt to be bent on a mandrel, the rounded end of which has a radius the same as that of the bolt.

Shank Fracture Test—The shank of these products may be fractured to show

¹The mean diameter is considered the mean between the root and pitch diameters.

visible defects such as piped steel, seams, or coarse crystallization. These defects will probably be visible to the naked eye or through a hand lens.

Impact Test—There are three classes of impact testing machines: (1) Drop weight; (2) pendulum; and (3) flywheel. These machines differ according to the method used to energize the moving mass. With each of the above classes of impact testing machines, there may be used four types of impact specimens, depending upon the way in which they are ruptured and the way they are held on the anvil: (1) Tension, (2) shear, (3) simple beam, and (4) cantilever.

Bolts, screws, and nuts are usually subjected to tensile impact service, but regardless of type, all impact testing should duplicate actual service conditions as far as possible, especially in method of supporting specimen, application of stress, and tightness of the nuts.

A common qualitative test to determine the core toughness of surface hardened parts is to subject the piece to hammer blows.

Ordinary steels increase rapidly in brittleness as the temperature is lowered to or below freezing. Accordingly, they should not be tested at a lower temperature than the one at which they are expected to show freedom from brittleness.

Torsion Tests—When it is necessary to test the torsional strength of these products, it is recommended that it be done so that the actual foot pounds can be measured. The test should be made on a torsion machine.

Shear Tests—Shear tests are best made in a special shear block in which holes in the block and plunger hold the specimen rigidly in alignment. The holes must be close fitting and the block and plunger of hardened steel. The block is used in the tensile machine.

Thread Stripping Test—The strip test for threads is applied to threaded sections, including nuts, and when possible it should be made in tension on assembled units.

Macrostructure—To determine the character of grain flow (in headed products) and certain internal conditions of the metal, the samples may be split longitudinally and etched deeply in hot hydrochloric acid (1:1). The presence of a pipe, segregation, and other defects will be revealed when a transverse section is etched. The interpretation of results should rest with those of experience in reading the effects of this test. For details, interpretation of results, and the correct etching time, see in this Handbook the Standard Macro-Etch Test for Iron and Steel.

Microstructure—The microstructure of the metal is studied to determine the internal condition of the metal, structure, and heat treatment. Photomicrographs at appropriate magnification record the conditions found. This method of testing is of much importance in determining the quality of sections, but the interpretation of results should be placed in the hands of experienced and trained technicians.

Inspection of Protective and Decorative Coatings—A protective coating may or may not be decorative. A decorative coating, however, must always be protective, because any coating which is not sufficiently protective soon loses its decorative quality.

The decorative quality of coatings is usually determined by visual examination.

The protective quality of a coating may be tested in several ways: (1) Outdoor exposure test, (2) salt spray test, (3) measuring the thickness of coating, (4) porosity test, and (5) the trichloroacetic acid test.

1. **Outdoor Exposure**—The outdoor exposure test, while quite reliable, usually involves more time than is permissible.

2. **Salt Spray**—The salt spray test is in general use for checking the corrosion resistance of coatings. The test should be conducted in a closed cabinet in which a solution of salt (NaCl), 20% by weight, is atomized continuously so as to give a visible fog in all parts of the cabinet. Pieces under test should be suspended or supported in such a manner that the solution will not be retained in pockets. The temperature should be approximately 70°F. The pieces which are to be tested should be free from all protective films other than the protective coating in question. The pieces should be left in the salt spray test until the first appearance of corrosion of underlying metal. The salt solution should be changed frequently to avoid concentration by evaporation or contamination with zinc chloride or iron chloride.

3. *Measuring the Thickness of Coating*—To determine if the coating is of sufficient thickness to give satisfactory protection, it may be measured under a microscope, by micrometer, or by chemical determination (strip tests). These tests are frequently used as a guide to coating practice.

4. *Porosity Test*—Coatings may also be tested for porosity. Porous coating, even though of sufficient thickness, will result in early failure. Porosity of coating is usually determined by microscopic examination or by means of ferroxy or similar papers.

5. *Trichloroacetic Acid or Porosity Test*—This test indicates porosity of nickel and tin plates over brass, bronze, or other copper alloys by the appearance of a blue color on immersing the part in a solution of 100 g. trichloroacetic acid and 700 cc. water.

At time of making the test add $\frac{1}{2}$ volume of ammonium hydroxide, sp.gr. 0.90, to one volume of the above stock solution. This solution should be used only once and should be discarded after making one test.

Chromium plated parts shall have the chromium plate removed before making the test. This may be done by immersing in hydrochloric acid until gas is no longer evolved, which signifies that the chromium is completely removed.

The time required for the blue color to appear is the measure of the quality of the plating from the standpoint of porosity.

Distribution of Results—It is known that when the results of testing many pieces of the same composition and heat treatment are plotted, the results tend to conform to the normal exponential distribution law. Therefore, it is impossible to specify too narrow ranges on any measured property without making allowance for the fractions having extreme values.

Thus, for example, in determining the Brinell hardness limits of a product with a 50-point range in a specification, 95% of the results might be found within the range. If only 40 points are allowed, only 85% might be included, and if only 30 points are allowed, only 70% may be found within the range.

Analytical Methods for Steel*

Explanatory Remarks—The methods described in this article are those selected after a critical study of the routine methods in use in several different laboratories as well as those adopted as referee methods. Of the former, only those that give results in close agreement with the latter have been included. Lack of space compels the omission of many details of manipulation and of the many variations that may be used in carrying out some of the procedures. To the well trained analytical chemist, these omissions are not essential, but when more complete details are required, the reference works given should be consulted.

Sampling—In commercial practice, particularly, the importance of care, good judgment, and cleanliness in sampling cannot be overemphasized, for it is self-evident that the most accurate analysis of a misrepresentative sample is worthless. Therefore, the sample must be taken in such a manner that it will be representative of the material sampled, and it must be prepared for analysis in such a way that it will be kept absolutely free of foreign material of any kind. Sampling of the molten steel as it is being cast into ingots affords the best opportunity, for obtaining a sample representative of the average composition, provided no additions are made to the steel in the molds. After the steel has been cast and forged or rolled the sample must be taken by milling or drilling. In general, milling of a complete cross section from a number of pieces selected from the lot is most satisfactory, particularly for small sections. To obtain a representative sample by drilling requires good judgment, as the method of taking the sample must be varied according to the kind of steel and the size and shape of the section. As a rule flats and shapes are sampled by drilling through the piece, and large sections by drilling in one or both ends, from some point corresponding to the locus of points midway between the center and the surface of the ingot.

Reagents—To save space reagents are designated by their chemical formulas, which are to be interpreted as representing either C.P. or reagent grade in solid or concentrated form as supplied by the manufacturers, chemically pure reagents being used for all standard solutions. Diluted solutions of the reagents are indicated in the several ways common to the profession. All water used is distilled water free from solids and having a pH value of 6.6 to 7. The pH of water saturated with CO_2 at room temperatures is near 5.

Determination of Carbon—Method and Limits of Error—Carbon in all kinds and types of steel is determined by direct combustion in oxygen. In routine and commercial analyses, the permissible variation in results from different laboratories is $\pm 0.01\%$, while results on the same sample of steel by the same laboratory should check to $\pm 0.005\%$. In referee work a tolerance of $\pm 0.005\%$ is permissible, because the limit of accuracy of the method for many kinds of steel is on the order of $\pm 0.003\%$. In analyzing steels containing less than 0.05% carbon, the limit of accuracy must be closely approached. Chemical knowledge, manipulative skill, and experience are required to obtain such accurate results on all classes of steel. Hence, except in referee work, carbon over 0.05% is reported only to the second decimal place.

Principle of the Method—Many variations as to details are permissible in both the apparatus and reagents used without exceeding the limits of error as noted above. The essential requirements are that a clean and representative sample of the steel be completely burned or oxidized in a stream of oxygen free of interfering substances and that the CO_2 resulting from this combustion be accurately measured. To measure the CO_2 evolved, it must be separated from other products of the combustion, particularly the oxides of sulphur and selenium, and from the excess oxygen. This separation is accomplished by removing the oxides of sulphur and selenium in an appropriate purifying train and absorbing the CO_2 from the excess oxygen in a suitable absorbing medium. The CO_2 is then measured either by weighing or by titrating with a standard acid. The direct gravimetric method is the favorite for both routine and referee work, and the following description is restricted to it and one volumetric method.

*Prepared by C. B. Francis, Chairman of the Subcommittee on Chemical Methods. The following contributors very kindly supplied methods for the preparation of this article: J. P. Gill, A. B. Frost, D. P. Bartell, C. H. Flickinger, F. R. Tyson, H. E. Slocum, C. W. Kneff, and T. S. Woodward.

Apparatus and Reagents—The essential parts of the apparatus used in this method are shown in Fig. 1. Apparatus and reagents suitable for use in the different parts of the train are as follows:

A. **Oxygen Supply**—Compressed or liquid; 99.5% O_2 ; free of CO , CO_2 , or any other carbon bearing matter. Must not contain hydrocarbons.

B. **Reducing Valves**—Several different types are manufactured.

C. **Oxygen Purifying Train**—Soda asbestos followed by anhydrous soda lime; followed by anhydrous $CaCl_2$; KOH followed by H_2SO_4 and $CaCl_2$ in order; or concentrated H_2SO_4 followed by KOH and $CaCl_2$. H_2SO_4 is renewed as soon as it becomes noticeably discolored.

D. **Mercury Trap**—Used to prevent back flow of oxygen.

E. **Electric Furnace**—A furnace capable of giving temperatures from 1000-1400°C. is preferable. Temperatures of 1000-1100°C. are satisfactory for carbon steels, provided the sample is composed of chips fine enough to pass a No. 10 sieve. For coarse drillings or chips and heat resistant alloy steels, a temperature of 1260°C., 2300°F., is most satisfactory.

F. **Rheostat**—Used for controlling temperature within operating limits. Several commercial types are available; must be adapted to current used and voltage.

G. **Pyrometer**—Determines the temperature of furnace within heating chamber external to the combustion tube. Temperatures up to 950°C. can be judged by eye, but not higher temperatures, which are in the white heat range.

Fig. 1—Schematic diagram of carbon combustion train for the gravimetric determination of carbon in steel.

H. **Combustion Tube**—The best size is 1 in. inside dia. x 28 in. Exit end reduced in diameter is desirable. Tubes of quartz are satisfactory for temperatures up to 1050°C. For higher temperatures tubes must be made of porcelain or refractory clay glazed to be gas tight and nonsoftening at temperature of operation. Inlet end of the tube is preferably provided with a metal breech connector; if a rubber stopper is used it should be provided with a suitable shield, or the end of the tube should be water cooled. For low sulphur (under 0.060%) steels, the last 2 or 3 in. of the exit end of the tube may be packed with ironized asbestos to oxidize and hold sulphur and iron oxide, but the sulphur must be burned out regularly (every 200 determinations) by drawing this end of the tube back into the furnace while passing O_2 . For high sulphur and alloy steels, the asbestos packing is not desirable, except for those containing selenium, the oxides of which are most effectively removed by such a packing if the temperature is held below 200°C.

I. **Boat and Lining**—Boats are made of porcelain, refractory clays or 18 gage sheet nickel (max. carbon 0.02%). If nickel is used, it is ignited at 900-1000°C. for 8 hr. or longer after forming. Approximate size outside, $\frac{3}{4}$ in. wide at top, $\frac{1}{4}$ in. deep, 4-6 in. long, with walls as thin as practicable.

The boat is lined with alkali-free alundum, 60-90 mesh, or with highest grade chromic oxide, crushed, sized, washed, dried and ignited. Both boat and lining must be thoroughly ignited and kept protected from dust and other foreign matter before using for a combustion.

J. **Purifying train for removing H_2O and oxides of sulphur and selenium**—For low sulphur steels (under 0.06%) with tube, H, packed with ironized asbestos, this train may consist of a tube packed with P_2O_5 , but the same drying agent is also placed in the CO_2 absorber. For high sulphur steels (over 0.06%), selenium steels, and alloy steels requiring high temperature, this part of the train must provide for

the removal of oxides of these elements. Details may be varied to suit conditions. Combinations that have given satisfactory results for the direct gravimetric method are: (1) Zinc shot (40 mesh) followed by CaCl_2 and P_2O_5 ; (2) glass wool, PbO_2 , zinc shot, dehydrite; (3) heated platinized silica gel followed by ironized asbestos and P_2O_5 or other desiccant (Slocum sulphur trap); (4) specially prepared MnO_2 followed by dehydrite, anhydron, or phosphorus pentoxide; and (5) a 50% solution of chromic acid in water preceded by a packing of asbestos for selenium steels and followed by dehydrite, or by H_2SO_4 and dehydrite. The last three are especially recommended, and, with the exception of No. 3, are easy to prepare. In the volumetric method, the drying agents are omitted.

Preparation of Slocum Silica Gel Catalyst and SO_2 Absorption Tubes—Pour 90 ml. of a 10% solution of platinum chloride upon 120 g. of silica gel (wheat size), stirring to coat evenly. Dry at 110°C ., and cool. Add 40 ml. formaldehyde (40%), heat to 110°C ., and repeat till the gel is of a uniform black color. Cool, wash until free from chlorides, and dry at 110°C . Pack the platinized gel loosely into a U-tube, 1.2 cm. I.D. x 30 cm., total length, with a wad of glass wool at each end. Connect one end of the U-tube to the combustion tube, surround with a heating coil to maintain optimum temperature of 440°C ., and connect the other end to the SO_2 tube, the latter being packed with ironized asbestos, glass wool, anhydron, and glass cotton, in the end connected to the CO_2 bulb.

K. Absorber Bulbs for CO_2 —Direct Gravimetric Method—Types known as the Fleming, Nesbitt, Miller, Midvale, and Newburgh are acceptable. Closed types are recommended. The weight of the absorber packed should not exceed 200 g. and another of the same type should be used as a counterpoise in weighing. The bottle is packed from the bottom up with glass wool, soda lime or soda asbestos, a thin layer of asbestos, the same desiccant as is used before it, and glass cotton. Soda asbestos, or ascarite, is recommended. A newly packed bulb is first aspirated with oxygen, then allowed to stand in the balance case 5 min., and weighed just before using.

Volumetric Method—The absorber consists of a 300 ml. Erlenmeyer flask and a modified Meyer bulb of 10 sections, one end of which carries a glass tube long enough to reach the bottom of the flask when inserted through a 2-hole rubber stopper. This tube is slightly bent so that when the bulb is inserted in the stopper the tube is parallel with the side of the flask. In operation the barium hydrate solution is introduced into the Erlenmeyer flask which is then connected through the second hole of the stopper to the combustion train and supported in an inclined position so that the tube on the end of the Meyer bulb is below the surface of the barium hydrate solution. An improved form of bulb consists of 8 sections, the first 7 of which are $1\frac{1}{4}$ in. in diameter outside and the last $1\frac{1}{4}$ in. to serve as a splash bulb to prevent the solutions from being carried out of the bulb. The first 7 sections of this bulb have a capacity of 50 ml., the volume of barium hydrate solution recommended in these methods.

L. Gas Flow Indicator—The functions of this item are to guard the absorber and to indicate the gas flow, which must not be permitted to cease during a combustion. They may be of the pressure gage type or of the bubble type. Concentrated H_2SO_4 is generally used in the latter.

Checking the Train—The train assembled ready for operation should be checked before use and regularly thereafter for leaks and blank. The blank is found by placing the boat, containing only the lining, in the tube and passing oxygen as in a determination. The train may not be used for routine work until the blank is 0.0005 g. or less, and correct result (tolerance $\pm 0.005\%$) is obtained on an authoritative standard sample. In referee work 2-3 blank determinations, omitting only the sample in the boat, should be made prior to each determination to establish the blank.

Weight of Sample—To simplify calculations some multiple of the factor $0.2727 \left(\frac{\text{O}}{\text{CO}_2} \right)$ is used, usually 1.3635 g. or 2.727 g., the latter for low carbon steels.

These are known as factor weights.

Use of Accelerators with the Sample—Before high temperature furnaces were available, various substances called accelerators were added to the sample to effect complete combustion and liberation of all the carbon. With a high temperature furnace, giving working temperatures over 1200°C ., the use of an accelerator is seldom

necessary, except for certain high alloy steels, when 0.5-1.0 g. of pure tin shot (20-40 mesh) is added, and has been proved the best yet found for the purpose.

Procedure—Direct Gravimetric Method—With the train properly set up and tested, boat and absorbing bulb prepared, proceed as follows: Spread a suitable factor weight of the sample upon the bedding in the boat. If the combustion must be made at temperatures under 1100°C ., or if the sample is of a high alloy steel, add 0.5-1.0 g. of tin shot as an accelerator. Insert the boat into the end of the tube and push forward 2 or 3 in., but not far enough to coat the cuttings with oxide. After allowing 1-2 min. for the boat and contents to warm, push forward to the hottest part of the tube and close the latter at once. Admit oxygen at the rate of about 400 ml. per min. until combustion is complete (2-3 min.), then reduce the flow to about 200 ml. for 5 min. Close the oxygen valve, disconnect the absorber bulb, let it stand in the balance case 3 or 4 min., then close and weigh it. The gain in weight of the bulb (minus the blank in referee work), multiplied by 20 or by 10, depending upon the factor weight used, gives the per cent carbon.

In the meantime, remove the boat and place it under cover to cool. If the sample has not been completely oxidized to give a thoroughly fused button or "pig", repeat the determination.

Volumetric Method—To permit the use of a constant volume of barium hydrate solution, the weight of sample is varied from 1-5 g. inversely with the carbon content. Introduce exactly 50 ml. of standard barium hydrate solution into the absorber and connect it to the combustion train. Place a proper weight of sample in the boat, insert the latter into the combustion tube as described above, and admit oxygen as rapidly as the gases can be bubbled through the barium hydrate solution. Keep the gas bubbling through the bulbs during the combustion, and immediately after reduce the flow to that at the start. Aspirate 5 min., then disconnect the absorber, wash down Meyer bulb with CO_2 free water, add 3 drops of phenolphthalein indicator solution and titrate with standard HCl solution to the complete disappearance of pink color. Subtract the number of ml. of acid used from the number used in a blank titration and multiply the difference by the factor corresponding to the weight of sample used, to find the per cent carbon.

Solutions and Blanks for the Volumetric Method—Barium Hydroxide Solution—Dissolve 11 g. of $\text{Ba}(\text{OH})_2$ in 250 ml. of boiling water. Cool, filter rapidly, dilute to 1000 ml. with CO_2 free water, and keep protected from unpurified air until used.

Hydrochloric Acid—Dilute 6 ml. of concentrated acid to 1000 ml. To standardize these solutions proceed as follows:

Introduce 50 ml. of the $\text{Ba}(\text{OH})_2$ solution into the Erlenmeyer flask, add 100 ml. of CO_2 free water, and titrate with the HCl solution, using phenolphthalein as indicator. Record the ml. of HCl used as the blank. Now run two or more samples of a standard steel as in a regular determination. Subtract the average of the closely agreeing results from the blank, and divide the difference by the known per cent of carbon in the standard steel to obtain the carbon factor of the solutions. This factor must be determined for each new lot of solutions made up.

Determination of Manganese—Manganese is determined by the bismuthate or the persulphate oxidation methods, both of which are equally accurate when properly applied and carried out. In routine work the limit of accuracy that can in general be expected is $\pm 0.01\%$, in referee work $\pm 0.005\%$. Hence, manganese is reported to the second decimal place.

In both methods the manganese, after separation from interfering elements, is oxidized to permanganic acid, which is titrated with ferrous sulphate solution (bismuthate method) or with sodium arsenite (both methods). This titration may be made visually or potentiometrically, the latter being an advantage when the solution is colored or manganese to be titrated is high (over 15 mg.). For obvious reasons, the following descriptions are restricted and adapted to the visual method of titration.

Apparatus, Solutions and Reagents Required

I. **For the Bismuthate Method—Apparatus**—200 and 400 ml. beakers, two accurately calibrated 50 ml. burettes, heaters and suction filtering equipment.

Dilute Nitric Acid (sp.gr. 1.135)—Dilute 280 ml. of HNO_3 (sp.gr. 1.42) to 1 l.

Dilute Nitric Acid (3%)—Must be free of nitrous fumes. Boil 40 ml. of the concentrated acid; cool, and bubble clean pure air through it for 5 min.; dilute to 1000 ml., add 1 g. sodium bismuthate and allow to settle. Keep in a cool, dark place.

Asbestos Filter—Shred asbestos; ignite gently; digest with HCl; wash with H₂O in a ribbed funnel with platinum cone; digest 5 hr. with HNO₃ (1:3); wash thoroughly with hot H₂O, and mix with water. To make filter use a carbon filter tube. Add enough asbestos suspension to make a thin tight filter, apply suction gently, and wash thoroughly with hot water, and the 3% nitric acid. Then wash with KMnO₄ solution and with the dilute HNO₃ till washings are colorless.

Bismuthate—Must contain active O₂ equivalent to 75% NaBiO₃, and be free of Mn and Cl.

Ferrous Ammonium Sulphate—Dissolve 12 g. Fe(NH₄)₂(SO₄)₂·6H₂O in a cold solution of 50 ml. H₂SO₄ (sp.gr. 1.84) in 950 ml. of H₂O.

Standard Potassium Permanganate Solution (0.03 N)—Dissolve 1 g. KOH in 1000 ml. and add 1 g. KMnO₄. Age 1 week and filter through purified asbestos pad. Dissolve 1 g. of Bureau of Standards sodium oxalate in 100 ml. of boiled and cooled 5% H₂SO₄ solution. Titrate cold with the KMnO₄ solution, stirring constantly, heat to 70°C. and add the last 0.5 ml. dropwise to a lasting pink end point. Titrate a blank H₂SO₄ solution in the same way, and subtract this blank from the ml. KMnO₄ solution used to titrate the oxalate. Calculate the manganese value of 1 ml. of the KMnO₄ solution. A normal solution of sodium oxalate = 67 g. per l. and 1 ml. of N KMnO₄ = 0.01099 g. Mn, or 1 ml. of 0.03 N KMnO₄ = 0.0003296 g. Mn.

Standard Sodium Arsenite Solution—Dissolve 2 g. of pure sodium arsenite in water, filter if necessary, and dilute to 1 l. Standardize against 20 ml. portions of the standard KMnO₄ solution in 100 ml. of the filtered 3% HNO₃ solution, to a clear greenish yellow end point, or against standard steels, one containing no chromium and the others about the same as the steels to be analyzed.

II. For the Persulphate Method—Standard Sodium Arsenite—Make up solution as above. Standardize against a standard steel. To standardize against standard KMnO₄ solution, add 20 ml. of the latter to a 200 ml. beaker with 1 g. of electrolytic or ingot iron of low but known manganese content, and run through as in a regular determination. The solution is adjusted so that 1 ml. = 0.1% manganese on 0.5 g. sample, or 0.05% on a 1 g. sample.

Acid Mixture—Add 200 ml. H₂SO₄ (1:1) to 425 ml. of H₂O, then add 125 ml. H₃PO₄ (85%) and 250 ml. of HNO₃ (sp.gr. 1.42).

Silver Nitrate—Dissolve 10 g. of AgNO₃ in 1000 ml. of H₂O.

Ammonium Persulphate—Dissolve 25 g. of (NH₄)₂S₂O₈ (95% or better) in 85 ml. of H₂O, and use fresh.

Zinc Oxide Emulsion—Mix water with pure finely powdered zinc oxide, rubbing to a paste in a mortar at first, until it is of about the consistency of cream.

Sodium Bicarbonate Solution—Dissolve 80 g. of NaHCO₃ in 1000 ml. of H₂O.

I. Bismuthate Method—Plain Carbon Steel, and Low Alloy Steels Containing Nickel, Molybdenum, and Not More Than 3% Chromium—Dissolve 1.0 g. of sample (2 g. for ingot iron and 0.2-0.5 g. for manganese steel) in 50 ml. of HNO₃ (sp.gr. 1.135) and add the same acid to another beaker for a blank. Boil till oxides of nitrogen are expelled, then cool and add NaBiO₃ until a decided pink color persists on heating to boiling. Boil 2 min., add SO₂ or NaNO₂ solution until clear, and continue boiling until free of oxides of sulphur or nitrogen. Cool to 15°C., add an excess of NaBiO₃, shake or stir for 1-2 min. and let stand about 3 min. Add 50 ml. of the 3% HNO₃ and filter through an asbestos pad or, preferably, a fritted glass filtering crucible, porosity 1-G-4. Wash with the 3% HNO₃ until washings are colorless, and (a) titrate with ferrous sulphate and permanganate if chromium is low or absent, or (b) with sodium arsenite if chromium is high.

(a). Add 3 ml. of H₃PO₄ and completely discharge the pink color with ferrous ammonium sulphate solution. Back titrate with standard KMnO₄ solution to a lasting faint pink end point. Add the same volume of ferrous ammonium sulphate solution to the blank and titrate with the standard KMnO₄ solution. Subtract the ml. of KMnO₄ used in the first titration from that of the blank, and multiply by the proper factor to give the per cent manganese in the sample.

(b). Add standard sodium arsenite solution rapidly until the pink color starts to fade then slowly to a clear greenish yellow color that does not change on addition of another drop of the arsenite.

(2). **Chromium-Vanadium and Stainless Steels**—Separate chromium and other interfering elements by (a) zinc oxide, (b) a bicarbonate, or (c) an ammonium persulphate separation, the first being preferred except when cobalt is present, where the last must be used.

(a). Dissolve 2 g. of sample in 40 ml. dilute H_2SO_4 (1:3), add 30 ml. dilute HNO_3 (sp.gr. 1.135), and boil free of fumes. Cool, transfer to a 250 ml. volumetric flask, partly neutralized with dilute ammonia (1:3) if preferred, and add zinc oxide emulsion with shaking until a heavy buff colored precipitate forms. Dilute to the mark, shake, allow precipitate to settle, and filter off 125 ml. of the clear solution through a dry filter, collecting the filtrate in a carefully calibrated flask. Transfer this filtrate to an Erlenmeyer flask, add 25 ml. of HNO_3 (sp.gr. 1.42), boil free of oxides of nitrogen, and continue as in (1) above, but do not dilute before filtering.

(b). Dissolve 1 g. of sample in 20 ml. of dilute H_2SO_4 (1:9) contained in a covered 300 ml. Erlenmeyer flask, and dilute to 100 ml. with boiling water. Immediately add from a burette sodium bicarbonate solution until a permanent precipitate forms, then 4-6 ml. excess according to the chromium present. Filter through a 11 cm. paper, and wash 2 or 3 times with hot water, ignore cloudiness in the filtrate. Heat filtrate to boiling, add gradually 12 ml. of HNO_3 (sp.gr. 1.42) and evaporate to about 25 ml. Complete the determination as in (1) above. A trace of manganese may remain on the filter, particularly if it is high, and too great an excess of the bicarbonate solution is added. Practice on standards is necessary to develop the proper technique.

(c). Dissolve 1 g. of sample in a 400 ml. beaker with 15 ml. of a mixture of equal parts of HCl and HNO_3 . Add 20 ml. of HClO_4 , evaporate to fumes, and fume strongly for 10 min. Dilute to about 250 ml. with hot H_2O , add ammonia until iron is just precipitated, then 5-10 g. of ammonium persulphate and 10 ml. excess ammonia to precipitate manganese. Boil 10 min., let settle, filter and wash with hot dilute ammonia. Dissolve precipitate with dilute HNO_3 to which sodium nitrite has been added or with dilute H_2SO_4 (1:9) saturated with SO_2 , and complete the determination as described in (1a or 1b) above. If cobalt is high, boil and reprecipitate with ammonia and ammonium persulphate before oxidizing the manganese.

II. Persulphate Arsenite Method—The procedure below is applicable to all alloy steels, except (a) those containing more than 3% chromium, (b) those containing more than 10% nickel, (c) the chromium-tungsten steels, and (d) low tungsten steels. For these steels the initial treatment is varied as follows:

(a) For manganese in stainless and heat resistant steels, the chromium is most conveniently separated by volatilization as follows: Transfer 0.5 g. of sample to a 250-ml. Erlenmeyer flask. Add 5 ml. of dilute HCl (1:1) and 20 ml. of HClO_4 (70%). Heat gently until the steel is dissolved and fume to oxidize the chromium completely. Cool slightly and add a small portion of NaCl or HCl , then fume again. Repeat these operations until the solution ceases to evolve brown fumes of chromyl chloride when the chloride is added. Rinse the wall of the flask with a fine jet of water, add 5 ml. of HClO_4 (70%), and fume to expel chlorides completely. Cool slightly, add 25 ml. of the acid mixture, dilute to 100 ml. with hot water and complete the determination of manganese as directed in the procedure below.

If care is exercised to expel all the chromium, the solution may be used for the direct determination of vanadium, or any other element except those forming volatile chlorides. Also, the chromium may be separated from the perchloric acid solution with lead perchlorate, and most of the perchloric acid in turn removed by adding potassium phosphate.

(b). Separate Cr as in 1-2 (a) or (b), add 30 ml. of the H_2SO_4 - H_3PO_4 - HNO_3 mixture to the filtrate, or an aliquot part thereof, evaporate to 100 ml. and proceed as directed in the procedure below.

(c). Separate manganese by dissolving in HNO_3 , precipitating with KClO_4 , and filtering on asbestos, or by proceeding as follows: Dissolve 0.5 g. of the sample in 12 ml. of dilute H_2SO_4 (1:9), immediately dilute to 100 ml. with boiling water, add 10 g. or more of ammonium persulphate, boil 10 min. and filter. In either case dissolve precipitate with dilute nitric acid containing sodium nitrite, boil, add 30 ml. of the acid mixture and proceed as directed under Procedure below.

(d). Heat 0.5 g. of sample with 50 ml. of dilute H_2SO_4 (1:9) and 3 ml. H_3PO_4 , add 30 ml. of H_2O and 5 ml. of HNO_3 , and boil till solution is complete, then proceed as for the solution below:

Procedure—Transfer the sample (1 g. or less for Mn up to 1.00% or 0.5 g. or less for higher percentages) to a 500 ml. Erlenmeyer flask, add 30 ml. of the H_2SO_4 - H_3PO_4 - HNO_3 mixture and warm till dissolved. Boil till oxides of nitrogen are expelled, then add 100 ml. of hot water, 10 ml. of AgNO_3 solution, and 10 ml. of $(\text{NH}_4)_2\text{S}_2\text{O}_8$ solution. Boil briskly 1 min. Cool to below 30°C . and titrate rapidly

with standard sodium arsenite solution to a clear yellow end point that does not change on adding another drop of the arsenite solution. Multiply the ml. of arsenite solution used by the proper factor to find the per cent manganese in the sample.

Determination of Phosphorus—Phosphorus is always separated as ammonium phospho-molybdate, following which separation it may be determined by titrating with standard NaOH and HNO₃ solutions or gravimetrically by redissolving and reprecipitating as magnesium ammonium phosphate, the former method being used in routine analyses and the latter in referee work. For steel of all kinds, the accuracy is on the order of $\pm 0.005\%$, yet long custom decrees that results for this element be reported to the third decimal place.

Solutions Required

Dilute Nitric Acid (sp.gr. 1.20)—Dilute 380 ml. of HNO₃ (sp.gr. 1.42) to 1 l.

Dilute Nitric Acid (2%)—Dilute 20 ml. to 1 l.

Potassium Permanganate—Dissolve 25 g. of KMnO₄ in 1 l. of water.

Ammonium Bisulphite—Dissolve 30 ml. in 1 l. of water.

Ammonium Nitrate—Dissolve 50 g. in 1 l. of water.

Potassium Nitrate—Dissolve 10 g. in 1 l. of water.

Dilute Ammonia—Dilute 50 ml. of NH₄OH (sp.gr. 0.90) to 1 l.

Ammonium Molybdate Solution—Mix 55 g. of MoO₃ (or 65 g. of 85%) with 150 ml. of H₂O and dissolve by slowly adding 150 ml. of NH₄OH (sp.gr. 0.90) while stirring constantly. Filter, if not clear, and add slowly to 750 ml. of cold dilute nitric acid (sp.gr. 1.20) while the latter is constantly agitated. Add 2 drops of a saturated solution of ammonium phosphate solution, let stand 24 hr. and filter.

Some prefer a neutral molybdate solution made by mixing 65 g. of (NH₄)₂MoO₄·4H₂O, 225 g. of NH₄NO₃, 15 ml. of NH₄OH, and about 600 ml. of water, warming, filtering, and diluting to 1000 ml.

Phenolphthalein Indicator Solution—Dissolve 0.3 g. in 100 ml. ethyl alcohol (50%) and neutralize with standard NaOH solution.

Standard NaOH Solution—Dissolve 6.6 g. of NaOH in 1 l. of water, add 1 ml. of a saturated solution of Ba(OH)₂ and let stand 24 hr. or longer. Filter rapidly into a container and keep protected from the air with a soda lime tube. Standardize against an authoritative standard steel, preferably of a composition similar to the steels to be analyzed. Adjust so that 1 ml. = 0.01% phosphorus on a 2 g. sample.

Standard Nitric Acid—Clear the concentrated acid (sp.gr. 1.42) of oxides of nitrogen by boiling or bubbling pure air through it and dilute 7 ml. to 1000 ml. Dilute to agree with the Standard NaOH solution.

Magnesia Mixture—Dissolve 50 g. of MgCl₂·6H₂O and 100 g. of NH₄Cl in 500 ml. of H₂O. Add a slight excess of ammonia, let stand 12 hr., filter if not clear, and make just acid with dilute HCl. Some use the sulphates, but the chlorides are best.

I. Procedure—Volumetric Molybdate; NaOH Method—1. *Carbon Steels*—Transfer 2 g. to a 300 ml. Erlenmeyer flask, and dissolve with 50 ml. dilute HNO₃ (sp.gr. 1.20). For very low phosphorus, use 4 g. of sample and increase the acid to 75 ml. Also, increase the volume of acid if it is more dilute or if neutral ammonium molybdate is to be used. With the latter and acid of 1.35 sp. gr., for example, use 120 ml. of acid for a 4 g. sample. Add an excess of KmnO₄, boil 2 min., and clear the solution by adding ammonium bisulphite solution dropwise. Boil free of oxides of nitrogen, cool to 65–70°C., and add 50 ml. of molybdate solution at 20–25°C. Mix thoroughly, cool, and shake, preferably mechanically, for 10 min. Allow the precipitate to settle and filter through a close filter, washing the precipitate out of the flask with 2% nitric acid. Wash the flask and filter free of acid, the latter about 10 times, with the KNO₃ solution. Transfer the filter and precipitate to a titrating tumbler, add about 25 ml. of H₂O and standard sodium hydroxide solution in slight excess. Thoroughly macerate the paper with a stirring rod, dilute to about 150 ml., add 3 drops of phenolphthalein indicator solution, and titrate the excess NaOH with the Standard Nitric Acid Solution. Subtract the ml. of acid from the ml. of NaOH solution used to find the phosphorus in hundredths of a per cent.

II. Alloy Steels—Tungsten and Vanadium Absent—Procedure A—Transfer 2 g. to a 300 ml. Erlenmeyer flask, add 40 ml. of dilute HNO₃ (sp.gr. 1.20) and heat gently. If the steel does not dissolve or the solution becomes dark or black, add

5 ml. HCl and continue heating till it is dissolved. Add 25 ml. HClO₄ (60%) and continue heating for 5-10 min. after fumes of HClO₄ have appeared, but avoid too high a temperature. If carbon or carbides do not dissolve, add a few crystals of NaClO₃ and boil for 5 min. after the last addition. Cool, add 40 ml. of H₂O, filter, wash, and add 25 ml. of dilute nitric acid (sp.gr. 1.20). The solution should be completely oxidized. To test it, add NaMnO₄ or KMnO₄ solution drop by drop until it is pink in color, the sodium salt being preferred on account of the low solubility of potassium perchlorate. Boil the solution, decolorize with the usual reducing agent added drop by drop, and cool somewhat. To provide abundance of ammonium nitrate and adjust the acidity, add ammonia until a slight precipitate forms, and acidify by adding an excess of 5 ml. of HNO₃. Cool, if necessary, to about 50°C., add 50-70 ml. of the ammonium molybdate solution, and complete as described in I above or in the gravimetric method given later.

Procedure B—The following procedure was developed many years ago and is still recommended for some steels, such as austenitic manganese and silicon steels.

Digest 2 g. of sample with 50 ml. dilute HNO₃ (sp.gr. 1.20) until action ceases. Evaporate and bake for 1 hr. at 190-210°C. Cool somewhat, add 25 ml. HCl, warm to dissolve the cake, and evaporate to a paste. To expel the chlorine, take up with 10 ml. of HNO₃, add 50 ml. of HNO₃, evaporate to the appearance of a slight scum, again add 50 ml. of HNO₃ and evaporate to the same point. Finally, add 50 ml. of HNO₃ (sp.gr. 1.20), heat gently till soluble salts are dissolved, filter, and wash with water containing a few drops of HNO₃ per l. Heat the filtrates and washings to boiling, oxidize with a few drops of 2% KMnO₄ solution, boil 2-3 min., clear the solution by adding ferrous sulphate solution drop by drop, boil 3 min., and cool. Add ammonium hydroxide until a slight precipitate forms, then acidify by adding 5-10 ml. of HNO₃, and proceed with the precipitation of the phosphorus as described above, adding a slight excess of ferrous sulphate and keeping the temperature of precipitation below 45°C. If traces of vanadium may be present.

3. *Alloy Steels—Vanadium Present, Tungsten Absent*—Treat as in 1 above up to the point of adding the molybdate solution, then cool to 15°C. instead of 60°C. and add 5 ml. of a 40% solution of FeSO₄·7H₂O. Shake, add 85 ml. of molybdate solution, and continue shaking for 10 min. Allow to stand at least 1 hr., preferably longer, and finish the analysis as in I above. Set the filtrate aside for 6-8 hr. to make sure all the phosphorus was precipitated.

4. *Alloy Steels—Presence of Tungsten*—Transfer 2 g. to a No. 4 casserole and add 20 ml. of HNO₃ and 40 ml. of HCl. Heat until all but WO₃ is dissolved, evaporate to dryness, and bake off excess acid. Cool, add 20 ml. of HCl, warm, add 40 ml. of H₂O, and boil 10 min. or longer. Filter into a 300 ml. Erlenmeyer flask and wash alternately 3 times with hot dilute HCl (1:1) and hot water and finally 3 times with hot water. Evaporate filtrate to 10-15 ml., add 20 ml. of HNO₃ and evaporate again. Repeat HNO₃ treatment, dilute and filter if not clear. Add ammonia (about 15 ml.) until iron precipitates. Add HNO₃ slowly while shaking until precipitate just dissolves, then add 3-5 ml. excess (about 20 ml.). If vanadium is absent adjust temperature to 65-70°C., add 50 ml. of molybdate solution and finish as in I above. If vanadium is present, cool to 15°C. and continue as directed in 3 above. Add to the final result 0.001% for phosphorus retained by the WO₃ precipitate.

II. **Procedure—Gravimetric Molybdate-Magnesia Method**—Treat 4 or 5 g. of sample as in I up to the precipitation of the phosphorus with molybdate solution and let stand 4 hr., or longer. Filter and wash flask and filter 3 times with 2% nitric acid, and 5 times with 5% ammonium nitrate solution. Dissolve precipitate into a 250 ml. beaker with 20 ml. of dilute ammonia (1:1) containing 2 g. of citric acid, and wash filter 5 times with dilute ammonia, 5 times with hot water and 5 times with dilute HCl (1:20). If solution is cloudy filter through same paper and wash with hot water. Burn off the paper in a platinum crucible, fuse with not more than 0.5 g. of Na₂CO₃, extract with 10 ml. of hot water, and filter into the ammoniacal solution. Evaporate to 75 ml., acidify with HCl, add 20 ml. of magnesia mixture, and cool in ice water. Make slightly ammoniacal, stir 5 min., add 5-10 ml. of ammonia and let stand in a cool place 6 hr. or longer. Filter, wash 3 times with dilute ammonia, and dissolve into original beaker with dilute HCl (1:1). Unless arsenic is known to be absent, add 1 g. of NH₄Br and boil down to 10 ml. or slightly less. Dilute to 75 ml., add 0.2 g. of citric acid and reprecipitate as before. After 6 hr. filter, preferably through a close paper containing a quantity of ashless

paper pulp, wash with dilute ammonia, and ignite slowly at first and finally to constant weight at 1050-1100°C. Weigh as impure $\text{Mg}_3\text{P}_2\text{O}_7$. Treat with HCl . If a residue remains, filter, wash with H_2O , ignite, and weigh. Add 4 or 5 drops HF , evaporate slowly, ignite, and weigh. Subtract any loss in weight of the residue from that of the impure $\text{Mg}_3\text{P}_2\text{O}_7$ and calculate difference to per cent phosphorus, using the factor 0.27861.

Determination of Sulphur—Sulphur, like phosphorus, is reported to the third decimal place, though if results on the same sample from different laboratories check within 0.005% for plain steel, or within 0.010% on some alloy steels, the work should be considered satisfactory except when the highest accuracy is desired.

This element is determined either volumetrically or gravimetrically, the procedures being entirely different in every respect. In general the volumetric method is applied whenever possible in routine work, and the gravimetric methods are used only for referee work and in the analysis of steels to which the volumetric method is not applicable, including all steels containing selenium and many high alloy steels, such as the Cr-W-V steels. During the last 12 years (1926-1938) several methods involving combustion in oxygen have been proposed and the method is now being employed to advantage for sulphur in certain alloy steels, but the method has not yet reached the standing of a standard procedure. It may become such in the future with the introduction of further refinements.

I. Volumetric Evolution Method—Applicable to carbon steels and to alloy steels which are rapidly dissolved by HCl and evolve all their sulphur as H_2S , facts that must be ascertained experimentally. Selenium and zirconium interfere. A few steels which fail to meet the essential requirement just mentioned can be made to evolve all the sulphur as H_2S by annealing the drillings as follows:

Wrap 5 g. of the drillings in an 11 cm. filter paper, place in a porcelain crucible, add a layer of sulphur free charcoal, cover tightly, heat for 20 min. at 950-1000°C., cool slowly and treat as described below.

Steels that dissolve slowly in dilute HCl , such as those high in copper, are dissolved in concentrated acid. Many steels will not evolve all their sulphur by any treatment and it is customary to apply a factor to the results obtained by this method, this factor being determined for each type of steel by analyzing a Bureau of Standards Standard Sample of the same type.

Solutions Required

Dilute HCl—Dilute 500 ml. (sp.gr. 1.19) to 1 l.

Ammoniacal Zinc Sulphate—Dissolve 100 g. of $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ in 500 ml. of H_2O and add 500 ml. of NH_4OH (sp.gr. 0.90). Filter.

Ammoniacal Cadmium Chloride—Dissolve 10 g. of CdCl_2 in 400 ml. of H_2O and add 600 ml. of NH_4OH (sp.gr. 0.90).

Starch Solution—Use a fresh wheat, potato, or soluble starch. Many lots, particularly of the last, have been found unsuitable. Make 5 g. into a thin paste with water and add slowly to 500 ml. of boiling water. Let stand 24 hr., decant clear solution, add 15 g. of KI and mix. Use within 2 or 3 days or add a preservative, usually 5 g. of ZnCl_2 or ZnSO_4 in 50 ml. of water.

Titration Solution—Either iodine or potassium iodate is satisfactory. Dissolve 4 g. of resublimed iodine or 1.12 g. of KIO_3 in a concentrated solution of 12 g. of KI and dilute to 1 l. It is standardized to the theoretical titer against Bureau of Standards sodium oxalate through 0.03N KMnO_4 solution, or directly against arsenious acid, and adjusted to a normality of 0.0312 so that 1 ml. = 0.01% sulphur on a 5 g. sample. When so standardized it is necessary to apply corrections for blank in all titrations. This drawback is overcome in practice by standardizing the solution against a standard steel of the same kind and type as the steel to be analyzed, but a solution thus standardized will in most cases give slightly erroneous results on steels much lower or higher in sulphur than the standard.

To standardize with arsenious oxide, dissolve 1.5435 g. of this oxide with 1.25 g. of NaOH in warm water, dilute to 1 liter, and titrate iodate as follows: From a burette, transfer 20 ml. of the KIO_3 solution to a 250-ml. Erlenmeyer flask, and add an excess of KI . (A stable 0.03119 N solution of KIO_3 is made by dissolving 1.1125 g. of the salt and 2 g. of NaOH in water and diluting to 1 liter.) Acidify by adding 2 ml. of HCl (1:1), rinse the wall of the flask thoroughly, and buffer the solution with 15 ml. of ammonium acetate solution (50%). Add KIO_3 solution to a clear colorless end point. With the theoretical titer a factor must be applied to all results,

1.05 being recommended as a reliable average for carbon steels. Applying this factor to the solutions gives a normality of 0.02963.

Apparatus—Fig. 2 shows a typical apparatus used.

Procedure—Transfer 5 g. of sample (some prefer 10 g.) to a sulphur flask and connect as shown in Fig. 2. To 150 ml. of water in the titrating tumbler add 10 ml. of the absorbent solution and introduce 80 ml. of HCl (1:1, 2:1, or concentrated) through the funnel tube. If the latter acid is used, equip the flask with a suitable type of return condenser. Heat gently until the sample is dissolved and boil ($\frac{1}{2}$ -1 min.) until the gas in the flask is displaced with steam. As soon as the delivery tube becomes hot to the touch, disconnect the flask and remove it from the heat, leaving the delivery tube in the absorber and titrating tumbler. If the solution in the tumbler has become warm, cool it to 20°C. or below. Place the tumbler under the titrating burette, add 5 ml. of starch solution and 40 ml. dilute HCl (1:1) and titrate immediately with the iodine or iodate solution to a permanent blue end point. The number of ml. of titration solution used, minus the blank, if theoretical titer is used, gives the sulphur in hundredths of a per cent. If the theoretical titer is used and a weight greater or smaller than 5 g., the number of ml. are divided by 100 times the weight of sample used and multiplied by 5 to find the per cent sulphur.

Fig. 2—Typical apparatus for determining sulphur by the evolution method. Left—sulphur flask. Right—absorber and titrating tumbler.

II. Gravimetric Methods—The gravimetric methods include those known as the nitric acid method, the Meinelke method, the ether method, and the fusion method. The first two are more commonly used in this country and are described below:

1. **Nitric Acid Method—Selenium Absent**—(a). **Carbon Steel**—Transfer 4.58 g. of sample to a 400 ml. covered beaker, add 50 ml. of HNO_3 and dissolve slowly by regulating the temperature. Start 2 blank determinations in the same way. Some also add about 1 ml. of Br or about $\frac{1}{2}$ g. of NaBr, or add the sample in small portions. When the steel is dissolved add 0.5 g. of NaNO_2 , if NaBr was not used, and evaporate to about 10 ml. Cool, add 30 ml. of HCl, and evaporate just to dryness. Then add 30 ml. more of HCl and evaporate to the first separation of ferric chloride and redissolve with about 5 ml. of HCl; or separate the HNO_3 by adding 40 ml. of HClO_4 (70%) and evaporate to fumes, fuming 10 min., and holding the temperature no higher than necessary. Dilute with 25 ml. of H_2O and reduce by adding an excess of sulphur-free zinc. Before the evolution of hydrogen ceases entirely filter and wash with 75 ml. of 1% HCl, heat to 70°C. and add 10 ml. of a 10% solution of BaCl_2 . Let stand 24 hr., filter on a close paper and wash the filter once or twice with cold 1% HCl and finally with hot H_2O until free of chlorides, keeping the washings separate. Evaporate washings to dryness. Take up residue in 1 ml. of HCl, dilute to 25 ml., add 1 ml. of BaCl_2 and digest at 80°C. for 5 or 6 hr. Filter on a close paper, wash free of chlorides with hot H_2O and ignite both papers in a weighed platinum crucible. Add 1 drop of dilute H_2SO_4 (1:1) and 1 ml. of HF and evaporate to dryness. Ignite and weigh as BaSO_4 . Subtract the average weight of the blanks and multiply by 3 to find the per cent sulphur.

(b). **Tungsten, Selenium, and Low Sulphur Alloy Steels Insoluble in Nitric Acid**—Provide for 2 blanks and proceed as follows: Dissolve 4.58 g. of sample by adding it a little at a time to a mixture of 50 ml. of HNO_3 and 45 ml. of HCl contained in a 600 ml. beaker, or, if tungsten steel, by adding it to the nitric acid, warming, and adding the HCl a little at a time. Evaporate to about 20 ml., add 30 ml. of HCl, evaporate to about 20 ml., add cautiously 2 g. of Na_2CO_3 (omit if tungsten is present) and evaporate to dryness. Bake at 100-105°C. about 15 min., cool, add 30 ml. of HCl and the same volume of water, and digest till soluble salts have dissolved. Filter and wash with hot dilute HCl (1:1) and hot water, and finally 3 times with hot water. Evaporate filtrate to dryness, and bake at 100-105°C. Add 20 ml. of HCl, warm and add 60 ml. of hot water. Stir and filter immediately through a close paper into a 200 ml. beaker. Wash with 2% HCl and hot water until free of iron stains, and finally 5 times with cold water. Add a small amount of fine paper pulp, stir in 20 ml. of 10% BaCl_2 solution and let stand 12 hr. or longer. Filter through a close double filter, and wash free of iron stains with a solution containing 10 ml. of HCl and 2 g. of BaCl_2 per l. Wash free of chlorides with a small jet

of hot water and ignite carefully to a red heat. Cool, weigh, test for SiO_2 as in II(a) above, deduct blanks and multiply by 3 to find the per cent sulphur.

2. *Copper-Potassium Chloride, or Meineke, Method*—For high sulphur alloy steels insoluble in HNO_3 . Generally, results by this method are low by 0.002% to 0.005% S.

Special Solution Required

Copper Potassium Chloride $2\text{KCl} \cdot \text{CuCl}_2 \cdot 2\text{H}_2\text{O}$	300 g.
Hydrochloric Acid	75 ml.
Water	1000 ml.

Add the salt to the mixture of acid and water.

Procedure—Start one blank with each sample until an average blank for each lot of chemicals is established. Add 2.748 g. of sample to 225 ml. of the double chloride solution at room temperature and stir mechanically until the metal is dissolved. Filter through a thin close pad of thoroughly purified asbestos and wash 3 times with warm 2% HCl solution. Transfer plug with residue to beaker. Add 25 ml. of H_2O and 2 g. of KClO_4 . Then add 10 ml. of HNO_3 and 20 ml. of HCl and heat to dissolve carbides, sulphides, and sulphur. Filter and evaporate filtrate just to dryness. Redissolve in 10 ml. of HCl , evaporate to dryness, and bake at about 110°C . for 20 min. Dissolve residue in 10 ml. of HCl and evaporate to 5 ml. Dilute to 100 ml. with water, bring to the boiling point and filter. Wash with warm water to a volume of 200 ml. To this filtrate add 20 ml. of a 10% filtered solution of BaCl_2 . Warm for 5 min. and let set overnight. Filter and wash with a cold solution containing 10 ml. of HCl and 20 ml. of 10% of BaCl_2 per l. Finally wash with hot water. Ignite and weigh as BaSO_4 . Subtract the blank and multiply by 5 to find the per cent sulphur.

Determination of Silicon—Various methods that have been used for the determination of silicon are the straight hydrochloric acid method, the straight sulphuric acid method, the nitric-sulphuric acid or "Drown's" method, the hydrochloric-sulphuric acid method, and the perchloric acid method. All can be applied to carbon steels, except the first, which requires application of a factor to results as obtained and cannot, therefore, be considered as a standard. Of the other methods all require some modification before they can be applied to tungsten steels, and those involving dehydration of the silica with sulphuric acid may give trouble when applied to some steels containing much chromium (over 3%) unless special precautions are taken to purify the silica.

Weight of Sample Used—To avoid calculations the use of factor weights are recommended, and in all methods the weight of sample is varied according to the silicon content. Therefore, use 4.672 g. ($10 \times$ the factor 0.4672) of steels containing less than 0.3% silicon, and 2.336 g. of steels containing more than 0.5% silicon. Between 0.3 and 0.5% either weight may be used.

I. *Methods Involving Dehydration of Silicic Acid with Sulphuric Acid*—Applicable to all steels except those containing tungsten and much chromium and carbon.

(a). *Procedure*—Transfer the sample to a 600 ml. beaker of the pyrex type, or to a 300 ml. casserole or evaporating dish of porcelain or platinum. If porcelain is used, select a vessel in good condition. Dissolve the steel with a large excess of HCl , HNO_3 , H_2SO_4 , or a mixture of H_2SO_4 and either of the other two, whichever does the work most quickly. When the metal has dissolved, add 25-40 ml. of H_2SO_4 (1:1), unless a mixture containing an equivalent amount of H_2SO_4 was used, and evaporate until copious fumes of H_2SO_4 are evolved, then push the salts beneath the acid with a rod and fume for 2 or 3 min. Cool somewhat, add 100 ml. of warm H_2O , stir until salts are dissolved, and filter immediately through a close paper. Scrub the container thoroughly with a policeman, and wash alternately with hot dilute HCl (1:20) and hot water, until salts are dissolved, and finally 3 times with hot water. In referee work, or if silicon is over 0.30%, evaporate the filtrate, fume, filter and wash as before to recover soluble silica. Transfer the filter or filters and contents to a clean, weighed platinum crucible, ignite carefully, cool and weigh as impure SiO_2 . Moisten this silica with 0.5-1 ml. of dilute H_2SO_4 , add 10-15 ml. of HF , and evaporate slowly in a bath of hot air. When the contents are dry, ignite as before, cool and weigh. The loss in weight represents pure silica, from which the per cent is obtained by multiplying by 10 or 20, according to the factor wt. used.

(b). *Procedure for Tungsten Steels*—Transfer 2.336 g. of the sample to a 375

ml. casserole and add 50 ml. of concentrated hydrochloric acid. Cover the casserole and heat until the sample is dissolved. Remove from the hot plate and add slowly 10 ml. of concentrated nitric acid. When violent action is over cover the dish and evaporate rapidly to dryness. When the solution is near dryness remove to a cooler side of the hot plate to avoid spattering, and bake to the absence of all fumes. After baking is complete, cool slightly and add 30 ml. of concentrated hydrochloric acid and 20 ml. of water. (If preferred 30 ml. of H_2SO_4 may be added, when the steel has been dissolved and treated with HNO_3 , and evaporated to fumes, cooled, mixed thoroughly with 5 ml. of HCl and taken up in 100 ml. of H_2O .) Heat and keep near the boiling point until all soluble salts have dissolved. Remove the dish from the hot plate, wash off the cover glass and adjust the volume to about 100 ml. with hot water. Filter on paper pulp with suction. Wash 4 times alternately with hot dilute hydrochloric acid (1:1) and hot water and finally 4 times with hot water. In special work evaporate the filtrate, filter and wash as before.

Place the paper containing the tungsten, silica and impurities in a 20 ml. platinum crucible and ignite at a dull red heat until the paper is gone and the residue in the crucible is yellow in color. Cool in a desiccator and weigh. Ignite again for 15 min. at a dull red heat to insure constant weight. Volatilize silica as directed above, finally igniting at a dull red heat, not over 800°C .

II. Method Dehydrating with Perchloric Acid—Applicable to all steels except tungsten steels.

Procedure—Transfer the sample to a 400 ml. beaker of heat resistant glass. Add 30 ml. of HNO_3 (1:3) and add if necessary to effect solution 5-10 ml. of concentrated HCl . Warm on the hot plate until sample is in solution, remove from the plate and add 30-50 ml. (according to the size of sample) of 70% perchloric acid, c.p. Cover with a watch glass, return to the hot plate and evaporate to heavy fumes of perchloric acid. Continue to heat for 10-15 min., keeping the liquid hot enough to maintain a steady reflux of the acid on the wall of the beaker. Cool, add 100 ml. of H_2O and warm until all soluble salts are in solution. Filter at once and rapidly (suction), using paper pulp, wash well with warm dilute HCl (2%), and complete the washing with hot H_2O .

Ignite carefully and thoroughly, as the HClO_4 , not washed out of the silicic acid may cause popping and loss of silica. Complete the determination as directed in I(a).

Determination of Silicon and Tungsten—Three satisfactory methods are used, which are as follows:

I. The $\text{HCl-HNO}_3\text{-Na}_2\text{CO}_3$ Fusion Method—This method is applied to steels containing 1-6% tungsten; for steels containing 1% or less, it is better to determine Si and W on separate samples.

Procedure—Transfer 2.336 g. (factor weight for silicon) to a 375 ml. casserole or an unetched heat resistant beaker, and treat as described for silicon in tungsten steels. After volatilizing silica and determining silicon, fill the crucible half full of sodium carbonate and heat at a low temperature for 5 min. At the end of this time raise the heat until the highest temperature of a Meker burner is attained and the contents of the crucible fuse. Maintain in quiet fusion for 5 min. longer. Grasp the crucible with the tongs and, by a slow rotating motion, spread the molten contents evenly up on the sides. When the fusion is solid, place carefully in a 250 ml. beaker containing 150 ml. of water. Digest at a temperature just below the boiling point until the fusion is disintegrated. Remove the crucible and heat until everything except the precipitate of iron is dissolved. Filter on an 11 cm. ashless filter paper and wash 5 times with hot water. Ignite the paper and contents in the same crucible at a high temperature. Cool and weigh. The loss in weight is tungstic acid.

$$\frac{\text{WO}_3 \times 0.7931 \times 100}{2.336} = \% \text{ W}$$

II. The $\text{HCl-HNO}_3\text{-Cinchonine-Na}_2\text{CO}_3$ Fusion Method—This method differs from the preceding mainly in the use of cinchonine, the purpose of which is to precipitate all the tungsten. A blank determination should be made on each lot of chemicals, especially the sodium carbonate.

Special Solution Required—Dissolve 25 g. of cinchonine in 200 ml. of dilute HCl (1:1). For a wash solution dilute 30 ml. of this solution to 1000 ml. with hot water.

Procedure—For 10% W, or more, weigh a 2 g. sample; for less than 10% W, weigh a 4 g. sample; for less than 1% W, use a separate sample for silicon. Dissolve in 100 ml. of HCl, keeping volume at 100 ml. by additions of water. Oxidize with HNO₃ (5-10 ml.) dropwise, until the solution is completely oxidized. Evaporate to dryness, and bake. If only W is required, evaporate to a paste, take up in dilute HCl and again evaporate to a paste. Take the residue up in 60 ml. of HCl (1:1), digesting until the soluble portion dissolves. Then add 2 drops HNO₃. Add 100 ml. of hot water, 5 ml. of the cinchonine solution, and boil a few minutes until the WO₃ is clean and yellow. After the WO₃ has settled, filter through a No. 42 Whatman paper. Put ¼ of a paper (11 cm.) that has been macerated in hot water, in the apex of the filter. Wash with hot HCl (1:4), which contains 10 ml. of cinchonine solution per l. Wash once with hot water. If any WO₃ adheres to the beaker, wipe it off with a small piece of paper moistened with NH₄OH, and then add this to the main WO₃ precipitate. Transfer to a platinum crucible. Ignite the WO₃ precipitate at a dull red at first, and finally at a full red heat. Weigh. Weight equals crucible + WO₃ + SiO₂ + impurities. Cover the residue with HF. Add 2 drops concentrated H₂SO₄. Evaporate slowly to dryness until all white fumes are driven off. Ignite at a full red heat as before. Weigh. Weight lost is SiO₂. Calculate the silicon, thus:

$$\frac{\text{Wt. SiO}_2 \times 0.4672 \times 100}{\text{Wt. of Sample}} = \% \text{ Si}$$

Gross weight now equals crucible + tungsten + impurities. Add to the crucible sodium or sodium-potassium carbonate equal to about 10 times the weight of the residue. Use only carbonate that gives no blank. Fuse completely and dissolve fusion in 100 ml. of hot water. Filter through a No. 42 Whatman paper, and wash with hot water. Ignite and weigh. In the absence of Mo the weight now is crucible + impurities, and the difference between these last two weights is the pure WO₃.

$$\frac{\text{WO}_3 \times 0.7931 \times 100}{\text{Wt. of Sample}} = \% \text{ W}$$

In the presence of molybdenum, treat the filtrate from the sodium carbonate fusion as for molybdenum in the presence of tungsten, determine the former as MoO₃, and subtract this weight from the weight of the WO₃.

III. The Perchloric Acid-Cinchonine-NaOH Solution Method.

Special Solutions Required—See Method II above.

Procedure—Transfer the sample, 2.336 g. if W is under 3%, and 1.168 g. if it is over, to a 400 ml. beaker and dissolve in 60 ml. of 1:1 HCl. When solution is completed, add HNO₃ dropwise until iron is oxidized, boil for a few minutes and add 25 ml. of HClO₄ (70%). Evaporate to fumes of perchloric acid and continue fuming for 2 or 3 min. Cool, add 150 ml. of H₂O and 25 ml. of HCl (1:1) and bring to boil. Add 5 ml. of cinchonine solution and digest for 30 min. or longer at 90-95°C.

Filter on a tight ashless paper, washing well with cinchonine wash solution. Dissolve the small amount of W which cannot be scrubbed from the beaker with a little NH₄OH and evaporate to dryness. After bringing into solution with 1:1 HCl add a few drops of cinchonine solution, bring to a boil and pour through filter. Transfer filter to a weighed platinum crucible and ignite at as low a temperature as possible until carbon is gone. Cool and weigh as SiO₂ + impure WO₃. Treat with 2 drops H₂SO₄ (1:1) and 3-5 ml. of HF. Evaporate carefully to dryness on a sand bath, ignite at 750-850°C., cool and weigh again as impure WO₃.

Dissolve the impure WO₃ in the crucible with 15 ml. of a 10% solution of NaOH, transfer to a small beaker, and dilute with H₂O to 75 ml. Filter on a small ashless paper, wash well with hot water and reserve filtrate. Dissolve oxides from paper into beaker, with hot 1:1 HCl. Precipitate with NH₄OH, boil, and refilter, washing well with hot H₂O. Ignite and weigh the residue, the weight of which must be subtracted from the weight of impure WO₃. If molybdenum is present or suspected, determine it as MoO₃ in the filtrate and deduct its weight from the weight of WO₃.

The difference between the weight of SiO₂ + impure WO₃ and the weight of impure WO₃, multiplied by 40 represents the percentage of Si if 1.168 g. sample was

used. If 2.336 g. sample was taken, multiply difference in weight by 20 to obtain per cent Si.

The difference between the weight of crucible and the corrected weight of WO_3 multiplied by the factor $0.679 \times 100 = \% \text{ W}$, if a 1.168 g. sample is used. For a 2.336 g. sample, the factor is 0.3395.

Determination of Tungsten in High Speed Steels—Transfer 1 g. of drillings to a covered 250 ml. beaker, add 50 ml. of HCl and heat to incipient boiling. Place the beaker on a warm spot and add a few drops of HNO_3 , and wait until the vigorous action subsides. The addition of HNO_3 results in the momentary formation of brown ferric compounds which are quickly reduced again with the production of unstable dark green compounds. When this change takes place, repeat the treatment with HNO_3 until it ceases to recur. In this way the whole of the iron is oxidized with the production of a perfect solution of it and the tungsten and with the use of very little more HNO_3 than is required for the oxidation of the iron only. Evaporate the liquid as quickly as possible until tungstic oxide begins to separate and then add 10 ml. of cinchonine solution, afterwards boiling more slowly until 20 ml. is reached. Add then 100 ml. of hot water and set aside for at least 15 min.

Filter through paper pulp, wash with 5% HCl and water; dry and ignite in a platinum crucible; remove the silica with HF alone, ignite again and weigh. Cover the residue with about twice its weight of dry sodium carbonate and place the crucible in the hottest part of the muffle for 5 min. When the fused mass is cold, extract with hot water and filter. Ignite the washed residue in the same crucible. In the absence of molybdenum the loss in weight is tungstic oxide.

$\text{Weight of } \text{WO}_3 \times 0.7931 \times 100 = \% \text{ tungsten.}$

If the steel contains molybdenum, treat the filtrate from the sodium carbonate fusion as directed for molybdenum in the presence of tungsten (p. 702), determine the molybdenum as MoO_3 , and deduct this weight from the weight of WO_3 .

Determination of Copper—Copper is determined by several methods known as the CuS gravimetric method, the CuS electrolytic method, the CuS -iodide-thiosulphate method, the thiosulphate-KCN method, and the thiocyanate-iodate method. All give satisfactory results, but the first and the last only can be described here in detail. These two methods can be carried out in the ordinary laboratory, and no elements interfere when analyses are made with variations as noted.

I. CuS Gravimetric Method—(a). *Procedure for All Steels Except Tungsten Steels*—Transfer 5 or 10 g., according to the copper content, to an 800 ml. beaker, add 200 ml. of dilute H_2SO_4 (1:9), and heat gently. When solution is complete dilute to 500 ml., heat to boiling and saturate with H_2S for 30 min., as the solution cools. Digest 30 min., add paper pulp, filter and wash 3 times with dilute H_2SO_4 (1:99) saturated with H_2S .

(b). *For Tungsten Steels*—Dissolve 10 g. in 100 ml. of dilute HCl (1:1). Add 25 ml. of HNO_3 (1:1) and boil gently until precipitate is a bright yellow. Dilute to 150 ml. with hot water, digest 5 min., filter and wash with dilute HCl (1:9). Add 15 ml. of H_2SO_4 to the filtrate and evaporate to fumes. Cool, add 100 ml. of water, and, if necessary, filter and wash with dilute H_2SO_4 (1:20). To the clear filtrate add 5 g. of tartaric acid, neutralize with NH_4OH , add 5% by volume of H_2SO_4 . Heat just to boiling and pass H_2S for 15 min. Let the precipitate settle, then filter and wash as in (a).

Transfer the paper containing the copper sulphide precipitate, which may also contain some MoS_3 , to a 30 ml., tall form porcelain crucible, and ignite at 550°C . Fuse with 2-4 g. of an alkali-pyrosulphate. Dissolve melt in 25 ml. of dilute HCl (1:9), dilute to 100 ml., neutralize with 5% NaOH solution and add 0.3 ml. in excess. Boil 3 min. digest 20-30 min., filter and wash with 0.5% NaOH solution, discard the filtrate or reserve for molybdenum. Dissolve precipitate in 15-25 ml. of hot dilute HNO_3 (1:3), wash with hot water, add 5 ml. of H_2SO_4 and evaporate to fumes. Cool, dilute to 40 ml., add an excess of NH_4OH and heat to boiling. Allow precipitate to settle, filter, and wash with hot water. If precipitate is considerable in amount repeat by dissolving in hot dilute HNO_3 and again adding NH_4OH . Neutralize the filtrate or filtrates with dilute H_2SO_4 (1:1), add 4 ml. in excess and adjust volume to 100 ml. Heat to boiling and keep saturated with H_2S for 20 min. Filter and wash as in (a). Transfer filtrate to a weighed porcelain or quartz crucible. Ignite carefully to 900°C . Cool over a good desiccant and weigh as CuO . $79.89 \times$ the weight of CuO divided by weight of sample used gives the per cent Cu.

II. The Electrolytic Method—Transfer the ammoniacal solution to a 250 ml. electrolytic beaker. Neutralize with H_2SO_4 (1:1), add an excess of 8 ml. and 4 ml. of HNO_3 (1:1), weigh cathode and electrolyze 12 hr. with 0.5 ampere. Wash cathode with water, dip in alcohol, dry 1 min. at 100°C ., and weigh. Increase in weight $\times 100$ divided by weight of sample gives the per cent copper.

III. The KI-Thiosulphate Method—Dissolve ignited oxide in 5 ml. of HNO_3 . Warm and transfer to a 200 ml. beaker with 25 ml. of H_2O . Boil, add excess of bromine water and boil off. Add slight excess of dilute NH_4OH , boil to a faint odor, add 3 ml. of glacial acetic acid, boil 1 min., cool quickly and dilute to 100 ml. Add 6 ml. of 50% KI solution, and titrate at once with standard thiosulphate (3.9 g. per l., 3 days old, checked against a standard steel). When the brown color fades add 3 ml. of fresh starch solution, and titrate to disappearance of the blue color. Calculate per cent copper. One ml. of the sodium thiosulphate solution equals 0.001 g. of copper.

IV. Thiocyanate-Iodate Method—Solutions Required.

Starch Solution—Fresh, see under Sulphur.

Thiocyanate—Dissolve 50 g. of KCNS in 1000 ml. of H_2O .

Standard Iodate—Dissolve in order 2 g. of KOH and 20 g. of KIO_3 in 2000 ml. of H_2O and standardize against standard thiosulphate.

Standard Thiosulphate—Dissolve 68.75 g. of $\text{Na}_2\text{SO}_3 \cdot 5\text{H}_2\text{O}$ in 1000 ml. of H_2O . Standardize against Bureau of Standards sodium oxalate through KMnO_4 .

Procedure—Transfer 5 g. to a 750 ml. flask, and treat as follows:

(a). **Carbon and Low Alloy Steels**—Dissolve in 85 ml. of H_2SO_4 - HNO_3 mixture (167 ml. of H_2SO_4 and 666 ml. of 1.20 HNO_3 diluted to 1 l.) or 75 ml. of H_2SO_4 (1:10), hot. Dilute to 300 ml., add $(\text{NH}_4)_2\text{S}_2\text{O}_8$ until MnO_2 precipitates, boil 15 min. and reduce by adding 70 ml. of 25% sodium sulphite solution or 30 ml. of stannous chloride solution (250 g. of SnCl_2 , 500 ml. of HCl , 500 ml. of H_2O).

(b). **High Chromium Nickel Steels**—Dissolve in 50 ml. of a mixture of HCl and HNO_3 (equal parts), add 20 ml. of HClO_4 and 2 ml. of HF , evaporate and fume 10 min. under cover. Cool, dilute to 100 ml., boil 1 min., filter and wash with hot H_2O . Add NH_4OH until $\text{Fe}(\text{OH})_3$ persists after stirring. Add 10 ml. of H_2SO_4 (1:1), dilute to 300 ml., heat to boiling and reduce as in (a).

(c). **Tungsten Steels**—Dissolve with 50 ml. of HCl . Add slowly 15 ml. of HNO_3 (1:1) and boil until tungstic acid is a bright yellow. Dilute to 100 ml., digest 10 min., filter and wash with HCl (1:10). Add 10 ml. of H_2SO_4 to filtrate, evaporate, and fume 1 min. Add 400 ml. of H_2O , warm until salts dissolve, and reduce as in (a).

To the reduced solution add 25 ml. of thiocyanate solution, boil 5 min., and let stand 5 min. Filter on a close paper, wash flask and filter 10 times with cold 2% H_2SO_4 . Transfer filter and precipitate to flask, add 20 ml. of HCl (1:1), and 4 ml. of standard iodate for each 0.1% copper. Macerate paper thoroughly, dilute to 500 ml., and add 1 ml. of 10% KI solution for each ml. of iodate. Add standard thiosulphate slowly with stirring until iodine color fades. Add 5 ml. of starch solution, and continue titrating until the blue color disappears. If the thiosulphate is less than $\frac{1}{2}$ of the iodate, repeat the determination with more iodate. The difference between the iodate and thiosulphate represents iodate required to oxidize the cuprous thiocyanate, and each ml. of the latter equals 0.05% copper.

Determination of Chromium—(Silicon, Vanadium and Tungsten)—All the methods for chromium in steel are volumetric and differ only in the reagents used to oxidize the chromium and in the details of titrating the chromic acid with a ferrous sulphate solution. Under certain conditions silicon and tungsten or vanadium, or all three, may be determined on the same sample as the chromium, though in referee or special work results for each should be checked by another method.

Special Solutions Required (All Methods).

Standard Ferrous Ammonium Sulphate—0.1 Normal (Use in All Methods)—To make a 0.1 N solution transfer 39.114 g. of $\text{FeSO}_4(\text{NH}_4)_2 \cdot \text{SO}_4 \cdot 6\text{H}_2\text{O}$ to a 1000 ml. flask containing about 500 ml. of H_2O , add 100 ml. of dilute H_2SO_4 (1:1), shake until dissolved, and dilute to 1 l. The solution is oxidized slowly by exposure to the air, hence 40 g. per l. is generally used, unless provision can be made for storing the solution under pure hydrogen or nitrogen. This solution is best suited for titrating 30-100 mg. of chromium. For low chromium (under 3%) use half, and for high

chromium (over 10%) use twice as much of the salt, or one-tenth as much for chromium under 0.10%. If the solution is not stored under H_2 or N_2 , standardize every day it is used by titrating with the standard oxidant, preferably using blanks containing all the reagents treated as in a regular determination.

Standard Oxidant Solutions—Potassium Permanganate—Except when the end point is obtained potentiometrically, the chromic acid is reduced by adding a slight excess of the ferrous ammonium sulphate solution, which is then back titrated with a suitable oxidant, usually potassium permanganate. Potassium dichromate or ceric sulphate can be used in conjunction with suitable internal indicators. If the former is used, it must be purified and taken as the primary standard or standardized through permanganate against sodium oxalate. If ceric sulphate is used, it can be standardized against sodium oxalate direct by adding an excess and back titrating with ferrous ammonium sulphate solution, using ortho-phenanthroline ferrous ion (2 drops of 0.025 molar solution) as indicator. However, potassium permanganate standardized against Bureau of Standards sodium oxalate is still used almost universally, and is therefore selected as the standard. Usually a tenth normal solution is most convenient to use, though a slightly stronger solution may be employed for high chromium, and for minute amounts (under 0.01%) a 0.02 *N* solution is desirable. In any case the method of preparing the solution is the same, and will be described only for the 0.1 *N* solution.

Standard 0.1 Normal Potassium Permanganate—A 0.1 *N* solution requires 3.1606 g. of $KMnO_4$. In preparing the solution, however, about 3.2 g. are used, as the $KMnO_4$ is not absolutely pure and some is decomposed in making up the solution. For the same reasons it is well to prepare a dilute solution at the same time as the stronger solution to use in adjusting the concentration of the latter.

Dissolve the $KMnO_4$ in about 900 ml. of cold water and let age one week, or in hot water and let age 24 hr. Filter through a purified asbestos pad and dilute the stronger solution to 1 l. with the dilute solution. Standardize against Bureau of Standards sodium oxalate according to directions supplied with the sample and adjust strength by adding a calculated amount of the dilute solution. One ml. of 0.1 *N* solution is equal to 0.001734 g. of chromium, from which factor percentages may be calculated after proper corrections for blank, provided the chromium is all oxidized to chromic acid or H_2CrO_4 .

The standardization of the solutions should be checked by analysis of a standard sample of steel of approximately the same composition as the steels to be analyzed.

Weight of Sample—In all methods the weight of sample is varied according to the per cent of chromium likely to be present, about as follows:

For chromium under 0.5% use 5 g. sample.
For chromium between 0.5% and 1% use 3 g. sample
For chromium between 1% and 5% use 2 g. sample.
For chromium between 5% and 12% use 1 g. sample.
For chromium between 12% and 25% use 0.5 g. sample.

Perchloric Acid Method—The sample is brought into solution in various ways. If the steel dissolves readily in perchloric acid, transfer the sample to a 400 ml. beaker, and add 10 ml. of water and 20 ml. of perchloric acid (70%), adding an additional 10 ml. of the acid for each g. of sample in excess of 1 g. Cover, heat gently till sample is dissolved, then boil and heat at fuming temperature for 10 min. Cool somewhat, add 10 mg. of $KMnO_4$ crystals, cool rapidly, add 50-60 ml. of water and 0.5 ml. of HCl , and boil 3 min. Cool rapidly, dilute to about 300 ml. and titrate as directed below.

If desired vanadium may be estimated by treating as directed for vanadium and silicon by filtering and treating in the usual way.

For steels attacked by nitric acid, transfer the sample to a 400 ml. beaker and dissolve in 40-60 ml. of dilute nitric acid (sp.gr. 1.20), varying the acid according to the size of the sample. Then add 20 ml. of perchloric acid (70%) and 10 ml. additional for each g. of steel used, and proceed as directed above.

For steels not attacked by nitric acid, use HCl or a mixture of HCl (2 parts) and HNO_3 (1 part) with 20 ml. of water to dissolve the sample. Then add perchloric acid and proceed as directed above.

For stainless steels, and other high alloy steels, particularly those containing tungsten, transfer the sample (0.5 or 1 g.) to a 500 ml. flask, add 10-15 ml. of a mixture consisting of 1 volume of perchloric acid (70%) and 2 volumes of phos-

phoric acid (85%), and digest at 180°C. for 5 min. under a loosely fitting cover. Add to the clear green solution 15 ml. of a mixture of 1 volume of perchloric acid and 2 volumes of 80% sulphuric acid, and raise the temperature to 205°C. for 10 min. To the orange colored solution add 10-15 mg. of KMnO_4 crystals, swirl, and plunge intermittently into ice cold water to cool as rapidly as possible, then add 70 ml. of cold water, follow with 0.5 ml. of HCl and boil 5 min. Cool rapidly, dilute to 300 ml. with cold water, and titrate as directed below.

Persulphate Method—Transfer the sample to a 600 ml. beaker and dissolve in 50 ml. of dilute H_2SO_4 (1:4) or in 60 ml. of mixed acids (160 ml. of H_2SO_4 , 80 ml. of H_3PO_4 , and 760 ml. of H_2O). If tungsten is present and it is desired to determine chromium potentiometrically, omit H_3PO_4 . Heat until action ceases, add 5 ml. of HNO_3 , and boil free of nitrous fumes. If carbides persist or tungsten is present, evaporate to first separation of salts, dilute with 50 ml. of water, add 10 ml. of HNO_3 and again evaporate. Add 200 ml. of H_2O , filter and wash with water. To the filtrate add 20 ml. of a 1% solution of AgNO_3 , heat to boiling and add slowly while stirring a concentrated solution of ammonium persulphate until a permanent pink color develops. Boil 5 min., add slowly 5 ml. of dilute HCl (1:1) and continue boiling until the pink or brown color disappears, adding 2-3 ml. more HCl if necessary. Boil 10-15 min. longer, cool to room temperature, dilute to about 300 ml. with cold water and titrate as directed below.

Potassium Permanganate Method—Transfer the sample to a 400 ml. beaker, and dissolve in 50-120 ml. of dilute H_2SO_4 (1:5). Heat gently until action ceases, oxidize by adding HNO_3 dropwise, then add 20 ml. in excess. If tungsten is present digest (under cover) until the tungstic acid is a light yellow color, and boil 10 min. If much tungsten is present, dilute to 250 ml. with hot water, filter, and wash with hot water. Heat the filtrate to boiling and add dropwise a saturated solution of KMnO_4 until the solution is a deep pink color or a permanent precipitate forms. Cover and boil 20 min. Filter through a close filter of purified asbestos, wash well with cold 5% H_2SO_4 solution, dilute to 300 ml. and titrate as directed below.

Potassium Chlorate Method—Dissolve the sample with 50 ml. of dilute HNO_3 (sp.gr. 1.20) in a 600 ml. Erlenmeyer flask. Heat until residue, if any, is a light yellow color and free of black particles. If solution is slow, add HCl a few drops at a time to avoid an excess until solution is complete. Evaporate until a slight scum of ferric nitrate begins to form. Add 125 ml. of HNO_3 , and heat to boiling. Remove from the heat and add 3-4 g. of KClO_3 . Boil vigorously to a volume of about 50 ml. Cool, add 100 ml. of cold water, filter through a purified asbestos pad, and wash with cold water until the washings are colorless. Discard the precipitate of MnO_2 and WO_3 . Dilute the filtrate to 300 ml. and titrate as directed below.

Bicarbonate Separation for Low Chromium and Vanadium—Transfer the sample (5 g. or 10 g.) to a 500 ml. Erlenmeyer flask, cover, and dissolve with 60 ml. of H_2SO_4 (1:9). Add 140 ml. of boiling water. Add at once an 8% solution of sodium bicarbonate (about 36 ml.) until a permanent precipitate forms, and then add 4 ml. in excess. Boil 1 min. Filter through an 11 cm. paper and wash 3 times with hot water. Transfer filter to a 400 ml. beaker. Wash flask with 50 ml. of mixed acids used in the persulphate method above, and transfer to the beaker containing the paper. Add 5 ml. of HNO_3 , boil free of brown fumes, and filter through an asbestos mat. Wash filter with hot water, dilute to 200 ml. and oxidize chromium, as described under the persulphate method. Titrate with 0.02 *N* solutions as directed below.

Visual Titration of the Chromium and Vanadium—To the cold solution obtained by any of the preceding methods, add from a burette a slight excess (2 ml. or more) of standard ferrous ammonium sulphate solution. If enough is present, 1 drop will give an intense blue color when added to 1 drop of fresh $\text{K}_3\text{Fe}(\text{CN})_6$ solution. While stirring, titrate the excess with standard potassium permanganate solution until a faint pink end point is obtained which persists after stirring for 1 min. To correct the titration for dilution effect and color interference, boil the solution for 10 min., cool, dilute to original volume and titrate to the same end point as before. The number of ml. of KMnO_4 solution used in the first titration, minus the number used in the blank gives the ml. used in titrating the excess ferrous sulphate. This difference subtracted from the ml. of KMnO_4 solution equivalent to the total ml. of ferrous sulphate solution used gives the number of ml. of KMnO_4 solution equivalent to the chromium present. To find the per cent chromium, multiply this quan-

tity by 100 times the chromium factor for the permanganate and divide by the weight of sample used.

To determine vanadium, add 5 ml. of H_3PO_4 if not already present, and then 15-30 ml. of 0.03 *N* ferrous ammonium sulphate or equivalent. (Test for excess as when titrating chromium, 1 ml. of 0.03 *N* solution = 0.0015 g. of V.) Stir, add 8 ml. of 15% $(\text{NH}_4)_2\text{S}_2\text{O}_8$ solution, stir 1 min., and titrate with 0.03 *N* KMnO_4 solution to the same end point as before. Subtract the KMnO_4 used from that equivalent to the ferrous sulphate used, and convert the difference to per cent vanadium.

Potentiometric Titration of Chromium—Absence of Vanadium and Tungsten—In this method the chromium is titrated direct with ferrous ammonium sulphate solution, which is standardized against pure $\text{K}_2\text{Cr}_2\text{O}_7$ by the same method of titration. Vanadium, if present, is titrated as chromium, and tungsten held in solution with H_3PO_4 makes the end point hard to detect. Two types of potentiometric apparatus are available, namely; the Larabee and the Kelly, the latter being the older and the one in more general use. With the Kelly apparatus, the solution is usually prepared by the persulphate method, and the procedure is as follows:

Place the beaker containing the solution in position, and adjust apparatus to bring the needle or beam of light near the left end of the scale. Add the standard ferrous sulphate solution slowly until the indicator moves to the right and remains in this position. If the end point is overrun add standard potassium dichromate solution till the indicator moves back to the left, then the ferrous sulphate solution until 1 drop causes the indicator to move permanently to the right. Multiply the ml. of ferrous ammonium sulphate actually used in reducing the chromic acid by its chromium value times 100 and divide by the weight of sample used to find the per cent chromium.

Determination of Vanadium—Potentiometric Titration—Applicable to chromium-tungsten-vanadium steels.

Apparatus—These directions are written for the Kelly electrometric apparatus. Before titrating, flush out the calomel cell tube, so as to insure the purity of the electrolyte in the cell. The calomel cell contains a bottom layer of Hg, then a layer of Hg_2Cl_2 , and is then filled with a neutral solution of *N* KCl (74.55 g. per l). The other electrode is a platinum tipped wire, which makes contact with the external circuit.

Special Solutions Required—Standard Potassium Dichromate Solution—Dissolve 0.9626 g. of $\text{K}_2\text{Cr}_2\text{O}_7$ in H_2O and dilute to exactly 1000 ml. The $\text{K}_2\text{Cr}_2\text{O}_7$ should be recrystallized and either heated just to the fusion point or dried at 200°C . This solution should be renewed at least once a week. One ml. is equal to 0.1% of vanadium in 1 g. sample.

Standard Ferrous Ammonium Sulphate Solution—Dissolve 8 g. of $\text{FeSO}_4(\text{NH}_4)_2 \cdot \text{SO}_4 \cdot 6\text{H}_2\text{O}$ in 1000 ml. of H_2O containing 50 ml. of H_2SO_4 . The factor showing the relation of ferrous sulphate and potassium dichromate should be obtained each day by titrating a 30 ml. portion of the chromate solution.

To compensate for losses due to occlusion and incomplete oxidation, which may amount to as much as 0.02% vanadium, and also compensate other possible errors, it is well to check this solution against a standard steel of approximately the same composition as the steels to be analyzed.

Procedure—Dissolve 2 g. of sample in 100 ml. of dilute H_2SO_4 (1:4). When solution is complete, gradually add dropwise 10 ml. of HNO_3 (1:1). Boil until tungsten, if present, is completely oxidized to yellow tungstic oxide. Dilute to 200 ml. with hot H_2O , add 40 ml. of HNO_3 and boil for 1 hr. at such a rate that the final volume will be between 100 ml. and 125 ml. Longer boiling does no harm, provided the volume of the solution does not fall below 100 ml. Cool, dilute to 300 ml. with ice water and see that the temperature of the solution is $5-10^\circ\text{C}$. Titrate with the FeSO_4 solution as follows:

Lock the beaker containing the solution into position. Turn on the switch that controls the motor and release the galvanometer needle. Next press downward and make a half-turn clockwise on the 2 plunger switches on the front of the box. Then turn the knob that controls the resistance, so as to cause the galvanometer needle to come to rest at zero. Finally, add from the burette the ferrous ammonium sulphate solution, until the change in potential causes the needle to move to, and remain at the right extremity of the dial. Read the burette and calculate the percentage of vanadium.

Unless the operator is an expert it is best to back titrate with the standard

dichromate solution, as follows: Add a slight excess of the ferrous ammonium sulphate, and then add the standard dichromate solution slowly until the indicator (needle or light) returns to its original position. Finally, add the ferrous solution drop by drop to the first large movement of the indicator, which is taken as the end point. Multiply the volume of ferrous solution by its bichromate equivalent. Subtract the volume of dichromate used, multiply by 0.1, and divide by the number of g. in the sample and by 0.995 to find the per cent vanadium. The factor 0.995 compensates for the vanadium not oxidized by the nitric acid.

Umpire Method¹—Briefly this method is carried out as follows: Dissolve the sample (2 g. if V is over 0.1%, 5 g. if under 0.1%) in dilute H_2SO_4 (1:10) and make a bicarbonate separation. (See under manganese and chromium.) From this point carry a blank through all steps also. Transfer paper and precipitate to the original flask and dissolve in 20 ml. of HNO_3 and 5 ml. of H_2SO_4 by heating to fumes, adding HNO_3 if necessary to destroy all carbonaceous matter. Then expel HNO_3 , dilute to 40 ml., filter off tungstic acid, if present, and evaporate to 40 ml., neutralize with NH_4OH , add H_2SO_4 equal to 1% of the solution, and separate vanadium by electrolyzing in a mercury cathode cell (preferably Melaven type). When all iron has been removed from the solution (ferricyanide test), draw off the liquid, washing the mercury 3 times with H_2O . Add 1 ml. of H_2SO_4 , heat to 75°C ., and add KMnO_4 solution to a decided pink. Heat to boiling, pass SO_2 gas for 5 min., and drive out excess SO_2 with a current of CO_2 , or until escaping gas has no effect upon a very dilute solution of KMnO_4 . Cool the solution to 70°C . and titrate to first pink with 0.03 N KMnO_4 solution. Repeat reduction with SO_2 and titrate as before. Titrate the blank to the same end point and subtract. Multiply the corrected volume of permanganate used by its vanadium titer times 100 and divide by the g. of sample used to find the per cent vanadium.

Vanadium in High Chromium Steels—Direct Titration After Volatilizing the Chromium—Procedure—For vanadium up to 1%, use 2 g. of sample and 1 g. for higher percentages. Transfer the sample to a 250-ml. Erlenmeyer flask. For 2 g. add 10 ml. HCl and 50 ml. HClO_4 (58-60%). Heat to dissolve and fume to complete oxidation of the chromium. Cool somewhat and volatilize the chromium with NaCl or HCl as described under manganese, persulphate method. Transfer to a 400-ml. beaker, dilute to 200 ml., and stir in 5 ml. of orthophosphoric acid (85%). Add an excess of ferrous ammonium sulphate solution and oxidize the excess by adding 8 ml. of a 15% solution of ammonium persulphate. Titrate the solution with standard KMnO_4 solution to a faint pink end point persistent for 1 minute. Correct this volume for the blank, if required for accuracy, and multiply the difference by 100 times the vanadium titer of the permanganate solution and divide by the weight of sample used to find the per cent vanadium.

Determination of Nickel

I. Dimethylglyoxime Method—Special Solutions Required

Ammoniacal Dimethylglyoxime Solution—Dissolve 10 g. of dimethylglyoxime in 650 ml. of NH_4OH and dilute to 1 liter. Make up fresh every week. Recommended where large amounts must be used.

Alcoholic Dimethylglyoxime Solution—Dissolve 10 g. in 1000 ml. of ethyl alcohol (95%). Keeps indefinitely.

Weight of Sample—Use 0.25 g. for nickel over 8%; 0.5 g. for 3-8%; 1 g. for 1-3%; 2 g. for 0.1-1%, and 5 g. for less than 0.1% nickel.

Procedure—Transfer the sample to a 400 ml. beaker and dissolve with 30 ml. of HCl , if possible, or with dilute H_2SO_4 (1:1), dilute HNO_3 (sp.gr. 1.135), or mixtures of these. If none of these acids are effective, add dilute HNO_3 and 10 to 15 ml. of HClO_4 (60%). If HNO_3 is not used initially, heat the solution almost to boiling and add 10 ml., dropwise. Boil and evaporate to moist dryness. Add 30 ml. of HCl and boil to 15 ml. Dilute with 40-50 ml. of water and filter immediately. Wash with HCl (1:1) and hot water. Discard the filter and residue of silica and tungstic acid. In the absence of cobalt dilute to 150 ml.; if cobalt is present, add in addition 100 ml. of water for each 1%. Add 60 ml. of a 20% solution of tartaric or citric acid, and 15 ml. additional for each additional g. of sample, if more than 1 g. was used. Neutralize with ammonia, add 1 ml. excess, and acidify slightly with acetic acid. In

¹See Chemical Analysis of Iron and Steel by G. E. F. Lundell, J. I. Hoffman, and H. A. Bright, John Wiley and Sons, New York.

the absence of cobalt, heat to 70°C. and add 10 ml. of glyoxime solution, plus 5 ml. additional for each 0.01 g. of nickel present. While stirring add ammonia until slightly alkaline, and let stand in a warm place for not less than 15 min., and preferably for 1 hr. For low nickel let the solution stand 8-12 hr. If cobalt is present add the dimethylglyoxime in the cold, and let stand for at least 4 hr. If the precipitate does not have the characteristic red color, or if manganese is high (over 1%) dissolve with a hot solution of 20 ml. of HCl (1:1) and 5 ml. of HNO₃, wash, dilute to 300 ml., add 10 ml. of tartaric or citric acid solution and reprecipitate as before.

After settling proceed by either of the following methods:

(a). Filter on a weighed, close, glass frit crucible filter, keeping the crucible full of liquid, and wash with hot water to which 1 drop of ammonia has been added. Dry at 110-120°C. and weigh as NiC₂H₃O₄N₄, of which 20.32% is nickel.

(b). Filter through a paper, wash thoroughly with hot water, and transfer to a weighed crucible. Cover with another wet paper, heat gradually until the paper is charred, and ignite to constant weight at a dull red temperature. Weigh as NiO, of which 78.58% is nickel.

II. Silver-Nitrate Cyanide Titration Method—Not applicable to steels containing copper, cobalt or tungsten.

Solutions Required—*Citric-Sulphuric Acid*—Dissolve 400 g. of citric acid crystals in water, add 160 ml. of concentrated H₂SO₄ and dilute to 1000 ml. with water.

Potassium Iodide—Dissolve 50 g. in 100 ml. of water.

Standard Silver Nitrate Solution—Dissolve 5.789 g. of AgNO₃ in water and dilute to 1 l. One ml. is equivalent to 0.001 g. of Ni.

Standard Potassium Cyanide Solution—Dissolve 5 g. of KCN in water and add 5 g. of KOH to preserve the solution. Dilute to 1000 ml. with water. Standardize as directed below.

Procedure—Dissolve 1 g. of sample in 20 ml. of concentrated HCl. Oxidize with 10 ml. of HNO₃ (sp.gr. 1.13). Boil off fumes and evaporate to 15 ml. If silicon is high dissolve in 20 ml. of concentrated HCl and 2 ml. of HF. Evaporate to dryness and bake. Take up with HCl and oxidize with HNO₃ as directed above. Cool, add 50 ml. of the citric-sulphuric acid solution and dilute to 250 ml. Then add NH₄OH until the solution is just alkaline to litmus paper. Cool and add dropwise with constant stirring enough NH₄OH to give a distinct odor of ammonia. This excess of ammonia is important. Too little will give high results, too much will give low results. Add 1 ml. of the KI solution and stir. Then add exactly 5 ml. of the standard AgNO₃ solution from a burette. A pale yellow cloud of AgI will form. Titrate with the standard KCN solution, while stirring constantly, until the solution just becomes clear. Finally, titrate back with the standard AgNO₃ until a faint but distinct cloud of AgI is again formed. Calculate the total ml. of AgNO₃ used to ml. of KCN. Subtract this from the total ml. of KCN used. This difference, multiplied by the value of the KCN in terms of nickel gives the percentage of nickel in the sample.

Caution—The KCN changes with age. Hence, the theoretical titer is based on the AgNO₃, and the solutions must be compared daily as follows: Treat a nickel steel standard free of cobalt as directed above. Add the nickel equivalent of the AgNO₃ used to the nickel value of the standard, and divide the sum by the ml. of cyanide solution used to find the nickel value of 1 ml. of the cyanide.

Slight modifications in the procedure as outlined above permit titration and determination of the nickel photometrically. The exact procedure will depend somewhat upon the type of photometric apparatus employed.

III. Color Method—Applicable only to steels containing less than 0.10% nickel.

Procedure—Transfer 1.2 g. of drillings to a 400-ml. Erlenmeyer flask and dissolve in 60 ml. HNO₃ (1.13 sp. gr.). When nearly in solution add 15 ml. ammonium persulphate solution (22.5%) to destroy carbides, and cool as soon as the persulphate is decomposed.

Add a little water to cool somewhat, then add 20 ml. of NH₄OH and 3 ml. of 1% KCN solution. Mix by whirling the flask, and add 15 ml. of NH₄OH. Dilute to exactly 300 ml. in a volumetric flask, immediately filter off 50 ml. of the solution and transfer it to a 150-ml. Erlenmeyer flask.

To this solution add 3 ml. of a nearly saturated solution of dimethylglyoxime; whirl and add 5 ml. of sodium hypochlorite. Mix well and allow color to develop for several minutes. Transfer to a colorimeter or comparing tubes and determine the per cent nickel by comparison with a standard prepared as follows:

The Standard for Comparison—Add a measured amount of the standard nickel solution to a 50 ml. graduate and dilute to 50 ml. with water, adding 3 ml. of glyoxime and 5 ml. of sodium hypochlorite solution.

The Standard Nickel Solution—Mix 2550 ml. H_2O , 850 ml. HNO_3 , and add 1050 ml. NH_4OH . Add 1.9 g. KCN dissolved in 100 ml. H_2O , then 100 ml. of a solution of nickelous nitrate containing 0.336 of nickelous nitrate. Immediately add 850 ml. NH_4OH and dilute the whole to 17,000 ml.

One ml. of this solution is equivalent to 0.002% nickel when compared with a 1.2-g. sample of the unknown solution.

Determination of Molybdenum—Molybdenum may be determined gravimetrically, volumetrically, or colorimetrically. In the absence of interfering elements, the last method does not require a preliminary separation of the molybdenum, but is applicable only to steels containing small amounts. Hence, only the first two methods are used in the analysis of complex steels, and both involve a separation of molybdenum as sulphide. For molybdenum under 1%, the alpha-benzoinnoxime method as developed by H. B. Knowles¹¹ is used.

The following procedure is applicable to the largest number of the different types of steel.

Weight of Sample—The weight of sample used is varied from 1-5 g. according to the probable percentage of molybdenum present, to give 20-30 mg. of molybdenum.

Procedure—In the absence of tungsten transfer the sample to a 600 ml. beaker or flask and dissolve in 100 ml. of dilute H_2SO_4 (1:5) by heating gently until action ceases. Add 20 ml. of a 25% solution of ammonium persulphate and boil for 8-10 min.

In the presence of tungsten, dissolve the sample in 100 ml. of dilute HCl (1:1) and oxidize by adding HNO_3 dropwise, or by adding 20 ml. of dilute HNO_3 (1:1). Boil gently until the tungstic acid becomes a bright yellow, then either dilute to 150 ml. or evaporate just to dryness, take up in 10 ml. of HCl and add 50 ml. of water. Heat to boiling, filter and wash residue with dilute HCl (1:9). Reserve the residue. At this point some prefer to add 15 ml. of H_2SO_4 to the filtrate, evaporate to fumes, take up in 100 ml. of H_2O and filter off any additional residue on a small filter, which is washed with 1% H_2SO_4 , this precipitate being combined with the previous one. If the original solution was evaporated just to dryness, this step may not be necessary.

To recover molybdenum from the residue, fuse with sodium carbonate and take up in water and filter, or dissolve the residue on the filter with hot 5% solution of NaOH. In either case wash the paper with hot water, and once or twice with a little dilute H_2SO_4 . Add 5 g. of tartaric acid to the filtrate or solution, then neutralize with HCl or H_2SO_4 , adding an excess of 3 ml. of the former or 5 ml. of the latter. Heat to boiling and pass H_2S for 10 min. Filter, wash with dilute acid (1%) saturated with H_2S and reserve to add to the main portion of the molybdenum sulphide obtained as directed below.

The solution containing the bulk of the molybdenum may be treated by either of the following procedures:

(a). Add 5 g. of tartaric acid, neutralize with ammonia, make just acid with H_2SO_4 , and add 5 ml. excess for each 100 ml. of solution. Heat to boiling, pass H_2S for 30 min., dilute with an equal volume of hot water, continue to pass gas for 5 min. and digest at 60°C. for 1 hr.

(b). To the oxidized solution add ammonia until a slight precipitate of $Fe(OH)_3$ persists. Dissolve with a few drops of concentrated HCl and add 3 ml. excess. Bring the solution to a boil and pass H_2S gas through it. If the H_2S produces a deep red color, add more HCl, not over 1 ml. at a time, until the precipitate settles out readily. If the solution is too acid, the H_2S will not completely precipitate the molybdenum and the filtrate will be colored blue. In this case start the determination anew.

Separate the precipitate of sulphur and molybdenum sulphide by filtering through a close paper and wash with 1% H_2SO_4 or HCl saturated with H_2S .

If there is any doubt about the completeness of the precipitation of the molybdenum, boil to expel H_2S and reduce the volume to about 300 ml. Add 20 ml. of persulphate solution, boil for 10 min. and again pass H_2S for 15 min. Filter and wash as before. Transfer precipitates to a silica or porcelain crucible and ignite slowly and carefully to constant weight at a temperature not over 525°C. Complete the determination by either of the following methods:

(a). To the crucible add 10 ml. of HCl (1:1) and digest until dissolved. Wash

into a beaker and dilute to 50 ml. with H₂O. Boil. Now add a 5% solution of NaOH, until there are 2 drops in excess, using either litmus paper or phenolphthalein indicator. Filter, wash with hot water, burn off as before in the same crucible, cool, and weigh. Subtract the weight of impurities from the first weigh, and calculate difference to per cent Mo, using the factor Mo:MoO₃ = 0.667.

(b). Leach in 30 ml. of NaOH (4% sol.) for 30 min. on warm part of hot plate. Filter (suction, paper pulp) and wash free of NaOH, using phenolphthalein as indicator. Acidify with acetic acid, heat to the boiling point, and add sufficient lead acetate (4% sol.) to completely precipitate the molybdenum. Filter, preferably by suction, using paper pulp, and wash well with hot water. Burn off the paper slowly in front of the muffle (max. temp. 600°C.) and weigh as lead molybdate.

$$\frac{\text{PbMoO}_4 \times 0.2616 \times 100}{\text{weight of sample}} = \% \text{ Mo}$$

(c). *Presence of Arsenic, Vanadium, and Tin—Volumetric Method*—Destroy paper and oxidize the sulphide by digesting with HNO₃ and H₂SO₄ (5 ml.) until the solution is clear and light colored. Evaporate and fume to expel all HNO₃. Cool, dilute to 50 ml., add 0.01 g. of Fe₂(SO₄)₃, then NH₄OH until first appearance of reddish tint dispelled by stirring, and heat the yellow solution to boiling. Heat 75 ml. dilute NH₄OH nearly to boiling in a 250 ml. beaker, and pour the solution into it, stirring constantly. Add paper pulp, filter, wash with hot water, and reserve the filtrate. Dissolve the precipitate with hot H₂SO₄ (1:4), using as little acid as possible, then nearly neutralize, pour into NH₄OH, filter into reserved filtrate and wash with hot water as before. Neutralize the combined filtrates with dilute H₂SO₄ (1:1) and add an excess of 5 ml. for each 100 ml. of solution. Heat to boiling, add KMnO₄ solution until decidedly pink, and pass through a Jones reductor, collecting the reduced solution beneath a solution of ferric sulphate (0.1-0.2 g.) and phosphoric acid (5 ml.). Titrate with 0.03 N KMnO₄ solution, subtract blank, and calculate to per cent molybdenum. One ml. of 0.03 N KMnO₄ solution = 0.00096 g. of Mo.

Alpha-Benzoinoxime Method—Absence of Tungsten—Transfer 1 to 3 g. of sample to a 600-ml. beaker and dissolve in 50 ml. of H₂SO₄ (1:16). Heat and add HNO₃ dropwise to the decomposition of carbides and the oxidation of iron and molybdenum. To remove SiO₂, add a few drops of HF, and then 10 ml. of boric acid solution (4%). Boil, filter, if necessary, dilute to 100 ml., and reduce with FeSO₄ (about 0.5 g.) at room temperature. Cool to 5°C. and add 10 ml. of 2% alpha-benzoinoxime in ethyl alcohol, and 5 ml. additional for each 0.01 g. Mo present. While stirring, add bromine water to tint the solution, then add 5 ml. more of the alpha-benzoinoxime solution. Cool the beaker for 10 minutes longer stirring occasionally, add paper pulp, and filter rapidly. Refilter any of the first filtrate that may not be clear. Wash with 200 ml. of a cold, freshly prepared mixture containing 10 ml. of the alpha-benzoinoxime solution and 2 ml. of H₂SO₄. Transfer to a platinum crucible, cautiously dry, char the paper, and finally ignite to constant weight at 500-525°C. Digest with 5 ml. of NH₄OH, filter, wash with 1% NH₄OH, and ignite in the original crucible. Subtract the second weight from the first to find the weight of MoO₃, which multiplied by 0.667 gives the weight of Mo in the sample. To find per cent Mo, multiply the weight by 100 and divide by the weight of sample used.

Determination of Cobalt—There are several methods for the determination of cobalt. One of the methods recommended is that of Hoffman, in which the major portion of the iron is separated with ether, while the remaining iron and the copper are separated with cupferron, and the cobalt finally precipitated with alpha nitroso-beta-naphthol. However, the following method is still generally used for high alloy steels, such as high speed steel. The method is based on separation of cobalt from Fe, Cr, W, and V, with zinc oxide and the subsequent precipitation of the cobalt with alpha nitroso-beta-naphthol in HCl solution, in which nickel remains soluble. The procedure is as follows:

Procedure—Weigh 2 g. of the sample into a 400 ml. beaker, dissolve in 50 ml. of concentrated hydrochloric acid and boil to the absence of fumes. When solution is complete, oxidize the iron with about 10 ml. of concentrated nitric acid and boil to the absence of fumes. Cool the solution and add ammonia slowly while stirring until the precipitate of iron hydroxide formed dissolves with difficulty. Cool to room temperature and wash into a 500 ml. volumetric flask. Add slowly, with constant agitation of the flask, an emulsion of zinc oxide until an excess is present. As this point is approached the solution becomes milky and a slight amount in

excess produces a heavy voluminous brown precipitate. Dilute to the mark with water and empty into a 600 ml. beaker. Mix thoroughly by stirring. Let the precipitate settle and decant 250 ml. of the solution through a dry 12.5 cm. filter paper into a 250 ml. volumetric flask. When 250 ml., representing 1 g., have been filtered, this solution is transferred to a 400 ml. beaker and 5 ml. of concentrated hydrochloric acid are added. The solution is heated to near the boiling point, and the cobalt precipitated with alpha nitroso-beta-naphthol. Just before the solution is ready to precipitate dissolve 2 g. of alpha nitroso-beta-naphthol in 25 ml. of concentrated acetic acid. Heat the reagent gently and add it to the hot hydrochloric acid solution containing the cobalt. The cobalt is precipitated as a red compound. A portion of the excess reagent also precipitates. Two g. of alpha nitroso-beta-naphthol will precipitate 0.05 g. or 5.0% cobalt. If the percentage of cobalt is low, use a correspondingly smaller amount of the reagent.

Hold near the boiling point for 15 min., let settle and filter on an 11 cm. ashless filter paper, using paper pulp. The last portion of the precipitate and reagent is removed from the sides of the beaker with difficulty. Wash the precipitate 5 times alternately with hot dilute hydrochloric acid (1:1) and hot water and finally 5 times with hot water. If accuracy is not a requirement in the work, ignite in a weighted silica or porcelain crucible at a low temperature until the paper is gone, then at a high temperature for 30 min. Cool and weigh. The increase in weight is cobalt oxide, Co_3O_4 , contaminated with a small amount of iron.

Therefore, in accurate work purify the precipitate before or after igniting as follows: Transfer the precipitate to a 250-ml. beaker and dissolve it in a mixture of 15 ml. HCl and 5 ml. HNO_3 , boiling the solution down to a volume of 5 ml. Note the color of the concentrated solution, which will be of an intense green if 1 or 2 mg. of cobalt are present. To eliminate every trace of HNO_3 , add 25 ml. of HCl , and repeat the evaporation. Dilute the solution to 50 ml. and add dilute ammonia (1:1) dropwise to the precipitation of the small amount of iron. Dissolve the precipitate by adding 1 or 2 drops of dilute HCl (1:1), and reprecipitate by adding 1 or 2 ml. of a 50% solution of ammonium acetate and boiling. Filter and wash with 10 ml. of a hot faintly ammoniacal solution of ammonium acetate. Redissolve and repeat the precipitation. Wash as before, ignite, weigh, and subtract this weight from the weight of impure Co_3O_4 .

Weight of purified cobalt oxide, $\text{Co}_3\text{O}_4 \times 0.7343 \times 100 = \% \text{ cobalt}$.

The ignited oxide does not have the exact formula Co_3O_4 . If the weight of oxide is appreciable, it is, therefore, advisable to change the oxide to metallic cobalt by repeated ignition in hydrogen in a Rose-form crucible until the weight is constant.

Determination of Titanium—Titanium is determined by several different methods. The following is applicable to high chromium steels such as the stainless steels, and other alloy steels, containing no vanadium or tungsten.

Cupferron Method—Absence of W and V—In the absence of copper, transfer 0.5-1 g. to a 200 ml. beaker and add 100 ml. of 10% H_2SO_4 and heat until all action appears to have ceased. Cool the solution to 10°C ., add a little ashless paper pulp, and precipitate the titanium by adding dropwise a freshly prepared 6% solution of cupferron (ammonium nitrosophenylhydroxylamine, $\text{C}_6\text{H}_5(\text{NO})\text{ONH}_2$), stirring constantly until the precipitate assumes a reddish brown color. Fill the tip of an 11 cm. filter paper with paper pulp, filter the solution and wash filter and precipitate 10-12 times with cold 5% H_2SO_4 . Transfer the filter and precipitate to a 50 ml. platinum crucible and ignite at a temperature no higher than sufficient to destroy the carbon of the filter paper. Cool and add to the crucible about 1 g. of potassium pyrosulphate, fuse gently and dissolve the melt in 50 ml. of dilute H_2SO_4 (1:4). Cool the solution to room temperature and determine titanium colorimetrically as directed below.

In the presence of much copper, dissolve sample as above, then filter on a 9 cm. paper containing some ashless paper pulp, and wash paper and residue well with 10% H_2SO_4 . Cool the filtrate to 10°C . and precipitate with cupferron as directed above. Transfer the filter paper containing the residue insoluble in H_2SO_4 to the original beaker. Add 25 ml. of dilute HNO_3 (sp.gr. 1.135) and heat gently to dissolve copper. Add about 50 ml. of hot H_2O , neutralize with ammonia, add a slight excess, and heat to boiling. Filter and wash well with hot H_2O . Ignite the paper and residue at a low temperature just sufficient to burn off the carbon and add the ignited residue to the ignited cupferron precipitate, then fuse the combined

residues with potassium pyrosulphate, dissolve in dilute H_2SO_4 (1:4) and determine titanium as directed below.

Transfer the solution, which should not contain more than 0.005 g. of titanium (0.5% on a 1 g. sample, or 1% on a 0.5 g. sample) to a color comparison tube. Add 5 ml. of 3% hydrogen peroxide ("dioxygen") and mix thoroughly. To another comparison tube add 45 ml. of cold 10% H_2SO_4 , 5 ml. of the same hydrogen peroxide solution, and then add from an accurate burette measured amounts of standard titanium sulphate solution (1 ml. = 0.0005 g. of Ti), mixing after each addition, until the color of the standard is slightly less intense than the solution. Dilute the standard to the same volume as the unknown and mix. After preliminary comparison add titanium sulphate solution to the standard, adding, at the same time, an equal volume of 10% H_2SO_4 solution to the unknown, and mixing after each addition, until the colors match exactly. To find the per cent titanium in the sample, multiply the number of ml. of standard titanium sulphate solution used by 0.05 and divide by the weight of sample taken.

Procedure for High Titanium—Over 1%—Treat 1 g. of the sample for the separation of titanium with cupferron as directed above. Ignite the precipitate in a 100 ml. platinum dish at a temperature just sufficient to burn the paper completely. Cool, add 15 ml. of dilute H_2SO_4 (1:1), and 10 ml. of hydrofluoric acid (48%), then evaporate in an air bath to fumes. Rinse down the wall of the dish with cold water and again evaporate to fumes to expel any trace of HF. Add 50 ml. of water and filter if a residue remains. Wash with hot water and reserve the filtrate. Ignite the residue at low temperature in a platinum crucible and fuse with a little potassium pyrosulphate. Take up in dilute H_2SO_4 (1:4), add a slight excess of ammonia, and heat to boiling. Filter, if there is a precipitate, and wash with hot water. Dissolve the precipitate with a little hot dilute H_2SO_4 and add to the reserved filtrate.

Add to the solution containing all the titanium 1 g. of tartaric acid, make slightly ammoniacal, neutralize with dilute H_2SO_4 and add an excess of 2 ml. of the concentrated acid for each 100 ml. of solution. Saturate the solution with H_2S and separate any precipitate by filtering and washing thoroughly with H_2S water containing about 1% of H_2SO_4 and 1% of tartaric acid. Discard the precipitate. Now add to the solution ammonium hydroxide until there is an excess of 2 ml. and pass H_2S for 5 min. Stir in some ashless paper pulp and filter. Wash the precipitate well with ammonium sulphide containing about 1% ammonium tartrate and discard. Boil the filtrate to the complete expulsion of H_2S . Adjust the volume of the solution to 150 ml. and add 30 ml. of dilute H_2SO_4 (1:1). Cool to 10°C ., add some paper pulp, and precipitate titanium with cupferron as directed above, adding the cupferron until there is an excess as indicated by the formation of a snow white precipitate which rapidly disappears. Filter, wash 12-15 times with cold 5% H_2SO_4 , and then 5 times with 5% ammonium hydroxide. Transfer the paper and precipitate to a platinum crucible and gradually ignite to between 1050 and 1100°C . Cool in a desiccator and weigh. Multiply the weight of the TiO_2 thus found by 59.95 and divide by the weight of sample taken to find the percentage of titanium.

To check the results fuse with potassium pyrosulphate, take up in dilute H_2SO_4 (6%), and proceed by one of the following methods:

(a) Pass the solution through a Jones reductor into a solution of ferric sulphate and phosphoric acid, and titrate with 0.05 N KMnO_4 solution. Make a blank determination in the same way and correct. One ml. of 0.05 N KMnO_4 = 0.002395 g. of Ti. The presence of Fe, Cb, Cr, Mo, U, V, W, or nitrates gives high results.

(b) Aliquot the solution and determine titanium in a suitable portion colorimetrically. If results do not check, test for other elements such as zirconium and correct the titanium gravimetric result.

Determination of Total Aluminum—Aluminum is determined in various ways, usually as the oxide or the phosphate, or by titrating the quinolate, and the procedure up to the final precipitation must be modified not only for different kinds and types of steels, but also according to the final precipitation. When the final precipitation is to be made with 8-hydroxyquinoline, the procedure of Bright and Fowler¹⁰ is recommended, though many prefer to make the preliminary separations in other ways than with sodium bicarbonate and sodium hydroxide. For example, the following is recommended for steels containing high percentages of nickel and aluminum:

Dissolve 0.5 g. or 1 g. of the sample, according to the aluminum present, with dilute HCl (1:1). Filter, wash with water, ignite, and reserve the residue. Oxidize the filtrate with HNO_3 , evaporate, add HClO_4 , and continue the evaporation to fumes, adding a ml. of HF from time to time as required to volatilize all the silica. Dilute to 200 ml., add ammonia until the solution is almost neutral, and electrolyze over a mercury cathode until the solution is free of iron. In the meantime volatilize the silica in the reserved residue, ignite gently, fuse with acid sodium sulphate, dissolve, and add to the electrolyzed solution. Precipitate the aluminum in the combined solutions with 8-hydroxyquinoline, and determine the aluminum either gravimetrically or volumetrically as directed by Bright and Fowler.

The best of the older and more tedious methods are given below, the first being applicable to carbon and alloy steels containing Al, Cr, V, Mo, and Ni, and the second to any aluminum bearing steel, including those containing tungsten. Neither method is designed for the determination of small percentages, such as of Al and Al_2O_3 in carbon steels.

Ether-Carbonate-Sodium Peroxide Separations Followed by Precipitation with Ammonia—Dissolve 2 g. sample in 50 ml. of HCl (1:1). Oxidize with 10 ml. of concentrated HNO_3 and evaporate to a paste. Add 5 ml. of concentrated HCl, and again evaporate to a paste. Take up with 5 ml. of concentrated HCl, and rinse wall of beaker with 20 ml. of water. Transfer the solution to a separatory funnel, using not more than 10 ml. of water to rinse the beaker. In a separate room or in a space remote from open flames or anything heated to redness or to a glowing temperature add 50 ml. of ether to the funnel. Cool and shake well, keeping the solution cold. Let settle 1 min. Draw off into another separatory funnel the bottom or acid layer, which contains the Al, Cr, V, Ni, most of the P, and a little of the Fe. Discard the top or ether layer. To this second separatory funnel add 50 ml. of ether, cool, shake and cool as before. Draw off the bottom layer into a 400 ml. beaker. Avoiding open flames, evaporate the dissolved ether under a well-ventilated hood, then evaporate to a paste. Take up with 5 ml. of HCl (1:1), oxidize with 1 ml. of HNO_3 and dilute with cold water to 200 ml. Add Na_2CO_3 , until the solution is near the neutral point. Then neutralize with Na_2O_2 and add 3 g. in excess. Add 5 g. more of Na_2CO_3 , boil for 2 min., and let settle. Filter into an 800 ml. beaker, washing with a hot 5% solution of Na_2CO_3 . Dissolve the precipitate in 10 ml. of HCl. Dilute to 100 ml. with water. Again add Na_2O_2 , filter and wash as before. Combine the filtrates, which now contain the Al and Cr. To this filtrate add dilute HCl (1:1) cautiously until a cloudiness appears. Heat to the boiling point, and add HCl (1:4), until a drop of the solution shows a brown ring on "Instantaneous" tumeric paper, after 2 seconds. Add a little paper pulp and let the precipitate settle. Filter and wash with hot 5% NH_4NO_3 solution. To the filtrate add ammonia until alkaline to methyl red, boil, filter and wash to recover any $\text{Al}(\text{OH})_3$ not precipitated. Dissolve the precipitate on both papers with 15 ml. of hot HCl (1:1). Add 10 ml. of perchloric acid, evaporate to fumes and fume 10 min. Cool and add 50 ml. of cold water. Filter and wash with hot water containing a little HCl, keeping the volume under 100 ml. To the solution, add 3 drops excess NH_4OH . Heat to boiling and let precipitate settle. Filter and wash well with hot 5% NH_4NO_3 . Ignite carefully in a weighed platinum crucible, using a low flame until the paper is all burned. Then cover and ignite for 5 min. or to a constant weight at 1000°C . or higher. Weigh as Al_2O_3 , 52.914% of which is aluminum. Divide product by 2 to find per cent Al.

Bicarbonate and Sodium Hydroxide Separations Followed by Precipitation of Al as Hydrate or Phosphate—The sample is dissolved in dilute H_2SO_4 (1:9), and both the weight of sample and amount of acid used are varied according to the probable percentage of aluminum present. The acid used equals 10 ml., plus 10 ml. additional for each g. of sample. Thus, for carbon steels and alloy steels containing very little aluminum, 10 g. are dissolved in 110 ml. of the acid, while 2 g. is used for aluminum steels containing up to 1%, and solution is effected with 30 ml. of acid. To compensate for errors due to reagents and glassware, it is well to start a blank using ferrous ammonium sulphate equivalent to 2 g. of Fe, and dissolve in a minimum amount of H_2O containing 10 ml. of the acid.

Procedure—Transfer the sample to a 500 ml. Erlenmeyer flask, add the acid, cover, and heat gently. Nearly all of any arsenic present should escape as AsH_3 . When action ceases add 200 ml. of boiling H_2O , and heat to boiling. Add 8% solution of NaHCO_3 from a burette until a faint precipitate appears, then add 4

ml. more. Let settle, filter and wash rapidly with hot H_2O , discarding the filtrate, unless desired for Mn.

The insoluble matter on the filter paper contains all the Al, Cr, Ti, and Zr in the steel, and may contain in addition all the Ce, Cu, P, Sn, U, V, and W contaminated with more or less ferric iron, and Co, Ni, and Si, if present.

In the absence of tungsten and much chromium or vanadium, dissolve the precipitate with 20 ml. of hot HCl (1:8) and wash paper with hot H_2O , collecting solution and washings in a 400 ml. beaker. Ignite the paper at low temperature in an open porcelain crucible, brush into a platinum crucible, fuse with $K_2S_2O_8$ or $NaHSO_4$, and dissolve the melt in the reserved solution.

In the presence of tungsten or much chromium or vanadium, sluice the bicarbonate precipitate into a beaker. Reserve paper and dissolve precipitate in 5-15 ml. of HCl and oxidize carbides and tungsten by adding 5-7 ml. of HNO_3 dropwise to the hot solution. If a yellow residue remains indicating tungsten, dilute, filter, and wash with hot H_2O , reserving the filtrate. Transfer paper to a beaker, dissolve the tungstic acid with a minimum of NH_4OH , boil to expel excess, dilute, macerate paper, filter, wash with hot water and discard the filtrate. Place all the filter papers in a platinum crucible, ignite just until paper is burned, fuse with $K_2S_2O_8$, and dissolve the melt in the reserved filtrate.

Note: If preferred, the Fe and Mo and a part of the As, P, and Sn may be separated by an ether extraction as in the preceding method, and the filtrates containing the Al and Cr treated as directed below.

To the tungsten-free acid solution add SO_2 water (2 ml. or more) and boil to reduce any chromic acid, then add HNO_3 (2 or 3 ml.) and boil to oxidize iron. Add NaOH solution to the first appearance of the slightest precipitate, then pour into 80 ml. of a 5% solution of NaOH, stirring constantly. Boil 5 min., settle, filter and wash with 1% NaOH. If aluminum is high, dissolve the precipitate with HCl, reprecipitate with NaOH, and combine the filtrates. Discard the precipitate, which contains the Fe, Cr, Cu, Ti, and Zr or use for determining Cr, Ti, or Zr and treat the filtrate, which contains the Al, P, V, and part or all of any tin present, as follows:

Neutralize the filtrate or filtrates with HCl, add 5 ml. in excess, and evaporate to 250 ml., when the precipitate that forms on adding HCl should have been dissolved. Unless tin is known to be absent, pass H_2S into the hot solution, filter and wash with H_2S water containing a few drops of HCl. Discard any precipitate, boil the filtrate to expel H_2S , and determine Al by either of the following methods; the first being preferable only in the absence of vanadium and in steels of low phosphorus content.

(a) Add 3 or 4 drops of methyl red indicator solution, then dilute ammonia slowly, with constant stirring, until the color changes from red to yellow. Boil 1 min. If the color changes to red, add ammonia until it changes to yellow again, boil 30 sec., let settle, filter and wash with hot water. If Al is high, redissolve with HCl, add paper pulp and reprecipitate as before. Ignite both filters at low temperature in a weighed platinum crucible. Moisten with dilute H_2SO_4 , add 3 or 4 ml. of HF, evaporate and ignite to constant weight at $1000^\circ C$. or higher. Record this weight less any blank found as $Al_2O_3 + P_2O_5 + V_2O_5$. Fuse with $NaHSO_4$ or $K_2S_2O_8$, dissolve melt in H_2O , and divide into two equal parts. Determine P in one part, vanadium in the other, multiply results by 2, calculate to P_2O_5 and V_2O_5 , and subtract the sum from the impure Al_2O_3 . Multiply this difference by 52.914 and divide by the weight of sample to find the per cent Al in the steel.

(b) To the acid solution from the H_2S separation of Sn, add 0.5 g. $(NH_4)_2HPO_4$, 2 or 3 drops of methyl red indicator, ammonia until the solution is distinctly yellow, and dilute HCl (1:20) until it just turns red again. Add paper pulp, heat to boiling and add 20 ml. of a 20% solution of ammonium acetate. Boil 5 min., let settle (10 min.-2 hr.), filter and wash free of chlorides with hot 5% NH_4NO_3 . If vanadium is high, dissolve with HCl, dilute to 250 ml. and reprecipitate. Ignite the precipitate gradually to constant weight at $1000^\circ C$., and weigh as $AlPO_4$. Subtract any blank found, multiply by 22.11 and divide by the weight of sample used to find the per cent Al.

Determination of Selenium—Selenium may be determined with fair accuracy in several ways, but the following are generally used by the manufacturers of steels containing selenium. The procedure, with permissible variations, is as follows:

Transfer 5-10 g. of the sample to a 600 ml. Erlenmeyer flask or a covered 400 ml. beaker. Add 50-60 ml. of a mixture of equal parts of concentrated HCl and HNO₃. If the initial reaction is violent, cool in running water. When solution is complete treat by either of the following methods:

(a) Add 35 ml. of perchloric acid (70%) and evaporate rapidly until red chromic acid crystals separate or until perchloric acid vapors begin to condense near the top of the beaker or flask. Cool slowly, cautiously add 100 ml. of cold water, and agitate until separated salts are dissolved. To remove silica, cool, filter through a close paper, and wash with warm dilute HCl (1:1) and warm water to a volume between 150 and 175 ml. Add HCl equal to 70% of the solution, follow with 100 ml. of H₂O freshly saturated with SO₂, warm to 65°C. and allow to stand 3 hr. at this temperature. Cool to below 10°C., and separate the selenium as directed below.

(b) Evaporate the mixed acid solution to dryness on a water bath. Do not bake. Add 10 ml. of HCl (1:1) and 20 ml. of cold water, stir, and digest on the water bath till salts have dissolved. Filter through a close paper, wash 2 or 3 times with dilute HCl (1:1) and finally with water until free of chlorides. Discard the residue and dilute filtrate and washings to about 150 ml. with cold water. Add concentrated HCl equal to 70% of the volume of the solution (about 100 ml.) and pass a current of washed SO₂ gas through the solution at the rate of about 2 small bubbles per sec., holding the temperature at 20-25°C. (room temperature) and stirring frequently to granulate the selenium. After all the selenium has been precipitated and the solution saturated with SO₂, allow the precipitate to settle for 1 hr., then filter as directed below.

As a filter for collecting and weighing the selenium, prepare a Gooch crucible with thoroughly purified and washed asbestos of the amphibole variety, which has been dried and ignited at a temperature of 700°C., or higher. After the filter has been prepared, dry, ignite at 700°C, cool and weigh. Wash with water, dry at 90°C., and reweigh to check loss on ignition. Filter the solution containing the selenium through the crucible, washing the selenium upon the filter with warm dilute HCl (1:1). Then wash free of acid with warm water, 2 or 3 times with ethyl alcohol (95%), and once with ether. Dry the crucible in an air bath at 85-90°C. and weigh. Record the gain in weight as "impure selenium." To check the purity, ignite to constant weight at a temperature no higher than necessary to volatilize Se (690°C.), cool and weigh. If this weight is within 1 mg. of the ignited weight of the empty crucible, and the asbestos mat shows no marked discoloration, consider the selenium pure. Otherwise subtract the ignited weight of the crucible after volatilizing the selenium and record the difference as pure selenium. Divide the weight of pure selenium by the weight of sample taken to find the per cent selenium.

Determination of Columbium and Tantalum—The Umpire method recommended by the Bureau of Standards provides for the determination of columbium, tantalum, titanium and zirconium on the same sample. For details of this method, see "Chemical Analysis of Iron and Steel," by Lundell, Hoffman and Bright, John Wiley and Sons, New York. Most manufacturers of steels alloyed with these elements use the method of T. R. Cunningham which, with some minor modifications introduced by others, is carried out as follows:

Procedure—Transfer 2 g. to a 400 ml. beaker, treat with 30 ml. of HCl at 60-70°C., and, when all action has ceased, evaporate to a paste (approximately 15 ml.). Add 200 ml. of warm water (some prefer a 5% solution of HCl), stir, add 30 ml. of freshly prepared H₂SO₄, and boil 10 min. Without delay, stir in a little ashless paper pulp, and filter through an 11 cm. paper carrying a light bedding of the pulp. Wash 12-15 times with warm dilute HCl (1:20) and discard filtrate and washings.

Transfer the filter and residue to a 50 ml. platinum crucible, and ignite gradually to a dull red until the paper is completely burned. Add 5-10 ml. of perchloric acid (60%) and 10-15 ml. of hydrofluoric acid (48%), evaporate the HF in an air bath and finally heat on a sand bath until copious fumes of perchloric acid are evolved. Rinse the wall of the crucible with 5 ml. of H₂O, and repeat evaporation and fuming to expel all the HF. Transfer the contents of the crucible to a 250 ml. beaker with 100 ml. of dilute HCl (1:20), add 20 ml. of the H₂SO₄ (saturated solution of SO₂), and boil 5-10 min. Filter and wash as before, transfer paper and residue to a weighed 50 ml. platinum crucible, heat gradually till the carbon is burned, and ignite to constant weight at 1000-1050°C., cooling in a desiccator. If the

residue is uniformly white in color and titanium is known to be absent, consider it $\text{Cb}_2\text{O}_5 + \text{Ta}_2\text{O}_5$, and treat for the titration of columbium as described below. If the residue is discolored, fuse with 1-2 g. of $\text{K}_2\text{S}_2\text{O}_7$, dissolve the melt in 100 ml. of dilute HCl (1:20), and repeat the hydrolysis with H_2SO_4 , filter, ignite and weigh as before. Weigh as $\text{Cb}_2\text{O}_5 + \text{Ta}_2\text{O}_5$ (+ TiO_2 if titanium is present).

Fuse the mixed oxides with 15 times their weight of $\text{K}_2\text{S}_2\text{O}_7$. When the fusion is clear, cool somewhat, add 5 ml. of H_2SO_4 (sp.gr. 1.84), and heat on a hot plate until complete solution is effected. Transfer the solution to a dry 250 ml. beaker, and rinse the crucible with 15 ml. of H_2SO_4 . Add 1 g. of succinic acid, then 10 ml. of a saturated solution of succinic acid, stir and dilute to 100 ml. If titanium is absent, 10 ml. of H_2SO_4 may be added to the crucible, which is rinsed with 30 ml. of the acid, and the whole diluted to 200 ml.

Unless titanium is known to be absent, add an excess of KMnO_4 solution (2.5%) and 5 ml. of a 3% solution of H_2O_2 . If a straw to amber color develops, determine titanium colorimetrically, reserving all the solution. In the positive absence of titanium, this step is omitted.

The columbium in the solution is determined as follows: Prepare a Jones reductor with a zinc column at least 15 in. long. Wash 20-mesh zinc with water, then with dilute (2%) H_2SO_4 , and amalgamate for 30-40 seconds by immersion in 0.5% solution of mercuric chloride. This zinc is good for 5-10 determinations. Transfer the amalgamated zinc to the reductor, wash thoroughly with water, once with 10% sulphuric acid, and keep zinc covered with water. Mount the reductor in a 1 l. suction flask containing 25 ml. of ferric sulphate-phosphoric acid mixture (100 g. $\text{Fe}_2(\text{SO}_4)_3 + 150$ ml. of 85% H_3PO_4 per l.), so that the tip of the reductor is immersed in the mixture, and arrange to apply gentle suction as required.

Heat 150 ml. of a 20% solution of sulphuric acid to 70°C ., and the solution containing the columbium to 60°C . Open the stopcocks and, without allowing the zinc at the top of the reductor to go dry at any time, pass in succession 100 ml. of the warm 20% H_2SO_4 solution, the solution containing the columbium, 50 ml. of the warm dilute acid, and 100 ml. of hot water, closing the stopcock with the water just covering the top of the zinc. Without delay transfer the solution in the suction flask to an 800 ml. beaker, and titrate with 0.05 N KMnO_4 , which has been standardized against Bureau of Standards sodium oxalate. Now run a blank through the reductor and titrate in the same way, substituting 100 ml. (or 200 ml.) of 20% H_2SO_4 solution for the solution containing the columbium. Subtract this blank from the KMnO_4 solution used to titrate Cb and Ti and calculate the per cent Cb and the per cent Ta in the sample as follows:

1 ml. of 0.05 N KMnO_4 = 0.002333 g. of Cb , or 0.002395 g. of Ti .

Divide the weight of titanium found in the color test by 0.002395 to find the equivalent ml. of KMnO_4 solution and subtract to find the ml. of KMnO_4 used in titrating the columbium. Multiply this difference by 0.002333 to find the weight of columbium in the sample, which multiplied by 100 and divided by 2 (wt. of sample) gives the per cent columbium. Then multiply the weight of columbium by 1.4296 to find the equivalent weight of Cb_2O_5 , and the weight of any titanium by 1.668 to find the TiO_2 . Subtract the sum of these products from the weight of the mixed oxides to find the weight of Ta_2O_5 in the sample. Finally, multiply the weight of Ta_2O_5 by 81.94 and divide by 2 to find the per cent Ta in the sample.

Determination of Tin—Tin in steel is determined either volumetrically or gravimetrically, the former being generally restricted to routine or control analyses of steels in production. More refined methods are available but not practicable for use in production.

Volumetric Method for Control Purposes—(Copper Absent or Low)—This method is not applicable to steels containing more than the usual amount of residual copper.

Special Solutions Required:

Potassium Iodate (0.1 N)—Dissolve 3.57 g. of KIO_3 and 20.0 g. of KI in 1 liter of water.

Starch Solution—Mix 1 g. of wheat starch with a little water and add to 100 ml. of boiling water. Boil 1 minute, cool, and decant the clearer liquid for use. Prepare a new solution every 3 to 5 days as required.

Potassium Iodide Solution, 10%—Dissolve 10 g. of KI in 100 ml. H_2O .

Standard Potassium Iodate Solution 0.01 N —Dissolve 0.357 g. of KIO_3 and 2.0 g. of KI in about 200 ml. of water, add 0.4 g. of KOH and dilute to 1000 ml.

The solution is standardized and the tin factor established by treating known solutions of pure tin with tin-free iron or steel as directed in the procedure below. Each ml. of this solution is equivalent to approximately 0.0058% tin on a 10 g. sample.

Procedure—Either take the HCl solution from an evolution sulphur determination or transfer 10 g. of the sample to a 500-ml. Florence flask, add 100 ml. of HCl, insert a funnel trap, and heat almost to boiling until solution is effected. In either case, start a blank using approximately the same volume of water and unneutralized acid. As soon as the cuttings have dissolved cool rapidly to room temperature and add 5 to 10 ml. of the 0.1 N potassium iodate solution, according to the per cent tin expected, adding 10 ml. for 0.1% tin or more and 5 ml. for tin under 0.1%. After 5 minutes, add 2.5 g. of aluminum in granular form (20 mesh). As soon as the aluminum has dissolved, heat to boiling and boil gently 20 minutes. Cool the solution rapidly, add 10 ml. of a 10% solution of KI, 5 ml. of the fresh starch solution, and titrate to a selected end point with the standard potassium iodate solution. From the number of ml. of the iodate solution used subtract the blank, and multiply the difference by the tin factor to find the per cent tin.

Gravimetric Method—This method is applicable to carbon steels either copper-free or containing copper and in addition all other elements ordinarily occurring as residuals in the steel.

Caution—Care must be observed to avoid heating any of the solutions obtained in the following procedure above 100°C.

Procedure—Dissolve 5 g. of the sample in 100 ml. of dilute HCl (1:1), heating gently to hasten solution. As soon as the cuttings have dissolved, add 5 g. of KClO₃, continue heating until the odor of chlorine has disappeared, add 50 ml. of H₂O, and maintain the temperature of the solution at 100°C. for 30 minutes. Filter, wash the filter and residue with hot water, dilute the filtrate to 400 ml., and pass a rapid stream of washed H₂S through the solution for 1 hr. Let the precipitate settle, preferably for 8 to 10 hr. Then filter and wash the filter and residue free of ferrous iron with H₂S water containing 1% HCl by volume. Transfer the filter and contents to a porcelain crucible and ignite at a low temperature until the paper is completely consumed. Brush the ignited residue into a 250-ml. beaker, add 50 ml. of a mixture of equal parts by volume of HCl and HNO₃, and heat gently for 1 hr. or longer. Dilute slightly, filter, and wash thoroughly with hot water. Transfer the filter and contents to a weighed platinum crucible, ignite at a low temperature, and weigh. Add 5 drops of H₂SO₄ and 5 ml. of HF. Evaporate to dryness on a sand bath or in an air bath, and slowly ignite to a temperature of 850–900°C. Cool, weigh, and compare with the weight before the HF-H₂SO₄ treatment. From the last weight subtract the weight of the crucible, and calculate the difference to per cent tin.

$$\frac{\text{Weight of residue} \times 0.7876}{3 \times 100} = \% \text{ tin in the sample.}$$

Determination of Zirconium—Transfer 2-5 g. of sample to a 250-ml. beaker, add 30 ml. of HCl + 15 ml. additional for each g. of sample, and heat gently until the cuttings have dissolved. Dilute to 150 ml., cool to 20°C., add slowly and with constant stirring 2 g. of cupferron dissolved in 35 ml. of cold water or sufficient to impart a reddish brown color to the precipitate. Add paper pulp, filter, and wash with cold dilute HCl (1:9). Ignite the residue and fuse with K₂S₂O₇. Dissolve in 100 ml. of dilute H₂SO₄ (1:9), filter, and wash with some of the same acid. Add 2 ml. of H₂O₂ (30%) to the filtrate and 25 ml. of an 8% solution of (NH₄)₂HPO₄. Stir and allow to stand several hours on a sand bath at about 65°C. Add paper pulp and filter, washing thoroughly with a 5% solution of (NH₄)₂NO₃. Transfer to a weighed platinum crucible, dry, char, and ignite at 1050°C. for 15 minutes. Cool and weigh as impure ZrP₂O₇. Fuse with K₂S₂O₇, dissolve in 40 ml. of dilute H₂SO₄ (1:9) containing 5 ml. of H₂O₂ (3%). If titanium is present determine it colorimetrically, calculate it to Ti₂P₂O₇, deduct from the weight of ZrP₂O₇, and calculate the difference to per cent zirconium.

Determination of Lead—Of the several ways for determining lead in steel, the sulphide-molybdate method is selected as one of the most rapid and simplest procedures of widest application. Neither molybdenum nor many of the other elements occurring in steel interfere. For the determination of lead in complex alloy steels, the procedure given below may have to be modified by introduction of other steps.

Procedure—For lead between 0.10 and 0.30%, dissolve 5 g. of the sample in

100 ml. of dilute hydrochloric acid (1:1) contained in a 600 ml. beaker. For lead under 0.10%, use 10 g., and for lead over 0.40%, 2 or 2.5 g.

Boil and rapidly evaporate until iron salts crystallize, but do not bake. Add 300 ml. of boiling water, stir until all the salts have dissolved, and pass a stream of hydrogen sulphide through the solution for at least 5 minutes, but preferably until the solution has cooled to room temperature. Filter and wash the beaker and precipitate once with 1% HCl solution saturated with H_2S .

Place a 250 ml. beaker under the funnel and dissolve the precipitate on the paper with warm dilute HCl (1:1). Moisten the paper once or twice with hot dilute nitric acid (sp. gr. 1.20) and wash four or five times with hot water. Dissolve 2 g. of tartaric acid in the acid solution of lead chloride, neutralize with ammonia and add an excess of 5 ml.

Heat the ammoniacal solution to boiling, and add 10 ml. of a 5% solution of ammonium molybdate. Permit the precipitate to settle, then collect it, preferably, upon a weighed close (No. 4) glass frit filtering tube or crucible. Wash the filter and precipitate free of soluble salts, dry at $130^{\circ}C$. to constant weight, cool to room temperature in the balance case, and weigh. Record the increase in weight of the filter as $PbMoO_4$.

If the $PbMoO_4$ is collected upon a paper filter, wash with hot water containing a little ammonium nitrate, dry, ignite gradually with free access of air to a temperature no higher than necessary to burn off the paper, and weigh at room temperature. Rapid ignition at a high temperature may reduce the salt and volatilize part of the lead and molybdenum.

Multiply the weight of $PbMoO_4$ by 56.43, and divide by the weight of sample used to find the per cent lead.

Methods for the Determination of Oxygen, Nitrogen, and Hydrogen in Ferrous Materials*

General—The determination of oxygen, nitrogen, and hydrogen in ferrous materials is difficult, because the total amount to be determined is frequently a matter of only a few thousandths of one per cent by weight, and is further complicated by the variety of forms and combinations of the three gaseous elements that comprise the small total. Oxygen exists in steel chiefly as discrete particles (inclusions) consisting of oxides and silicates of iron, manganese, aluminum, and the alloying elements, the distribution of oxygen among these combinations varying with the composition of the steel and with the refining and deoxidation practice. Small amounts of oxygen also may exist in solid solution in the iron and in the form of gaseous compounds, chiefly CO, in small blow holes or fissures. Nitrogen occurs chiefly in the combined form (nitrides of the metallic elements) but small amounts may be present in solid solution and perhaps as elemental gas. Hydrogen seldom is present in amounts as great as 0.001% and it is not definitely known whether hydrogen exists in solid solution or combined as metallic hydrides.

In such a situation it is natural that the methods of analysis differ widely in basic principles and in intent. In the determination of oxygen, for example, some methods are intended for the isolation and separate determination of individual oxides whereas others yield a single value for total oxygen without attempting to determine its distribution among the various combinations that are present. Because of this diversity in aims and basic principles it has been difficult to establish the accuracy of the different methods. Attempts to do this by comparison of the results obtained from the same materials by different methods of analysis are of little value unless each method yields concordant results in the hands of different analysts, so that the results are representative of the method rather than of the technique and procedure of the individual analyst. The data of the recent co-operative study of methods for the determination of oxygen in steel¹ showed that most of the methods require further refinement and development in order that different analysts using the same method may obtain results in satisfactory agreement.

At the present time the choice of an analytical method, to use in attacking a problem of gases in metals, depends upon the item that is considered to be of most importance, whether it be the total gas content or the content of one or more of the individual compounds. Complete information regarding the total gas content and the distribution of this total among the various combinations is difficult to obtain and usually requires determinations by several methods of analysis.

Individual methods for the quantitative determination of oxygen, nitrogen and hydrogen in ferrous materials are described in the ensuing paragraphs. Methods that yield qualitative rather than quantitative data, for example microscopic and petrographic methods, are not included in this report.

Methods for the Determination of Oxygen and Oxides—Most of the work on the determination of oxygen and oxides has been concerned with samples of solid metal but some attempts have been made to determine the oxygen content of liquid steel. Herty² suggested killing a spoon sample of molten steel with an excess of metallic aluminum. Subsequent determination of Al_2O_3 in the solidified spoon sample furnishes a measure of the oxygen content of the liquid steel but sufficient data are not available to evaluate the accuracy of this method. Difficulty in sampling may be encountered because of segregation of the Al_2O_3 in the solidified spoon sample and it is difficult to avoid some oxidation of aluminum by oxygen from other sources than the oxides dissolved in the molten iron.

The determination of the amount and composition of the gases evolved during the solidification of molten steel also has received attention. In the method of Hare, Peterson, and Soler³ the sample of liquid metal is collected and allowed to solidify in an evacuated steel tube. Determinations of the oxygen evolved as CO during solidification of the sample were found to be in good agreement with determinations of oxygen by Herty's method. A similar procedure was described by Wüster and Piwowsky.⁴

Methods for the quantitative determination of oxygen and oxides in solid steel fall into two groups: (a) reduction methods and (b) residue methods. The first

*Prepared by the Subcommittee on Gases in Metals. The membership of the subcommittee was as follows:—J. G. Thompson, Chairman; J. Chipman, C. M. Johnson, B. M. Larsen, D. W. Murphy, M. A. Scheil, F. W. Scott, and F. M. Walters, Jr.

group includes the vacuum fusion and hydrogen reduction methods which depend upon the action of carbon or hydrogen at elevated temperatures to reduce the oxide constituents of the steel, with subsequent determination of the gaseous products of the reduction reactions. The second group includes the iodine, electrolytic, chlorine, mercuric chloride, and acid residue methods which depend upon the removal of the metallic constituents, because of their greater chemical activity or solubility, leaving a residue from which various compounds can be isolated and determined.

Vacuum Fusion Method—The vacuum fusion or hot extraction method for determining total oxygen in irons and steels consists of melting a sample in a previously degassed carbon crucible in a highly evacuated furnace in which the pressure is maintained at about 0.001 mm. of mercury or less. The method is based on the fact that at sufficiently high temperatures all the oxygen containing compounds in the sample are reduced by carbon and converted into gaseous oxides of carbon. The gases evolved during the reaction are pumped off and analyzed, and the quantities of carbon oxides are used to calculate the amount of oxygen in the sample. Since the temperature used in the determination of oxygen is sufficiently high to decompose any nitrides that may be present, nitrogen may be determined on the same sample if a suitable method is used for the analysis of the gases.

The method has developed fairly rapidly since its inception. The early investigations in this field were attempts to melt the sample in refractory crucibles, but Oberhoffer and Hessenbruch¹ showed that it was necessary to carry out the reduction in graphite because of the error introduced by the reduction of the refractory crucible itself. Jordan and Eckman² were the first to apply the high frequency induction method of heating, and also used a gravimetric method of analysis. Hessenbruch and Oberhoffer³ introduced a method of inserting the sample without the necessity of breaking the vacuum.

Since the amount of oxygen in some steels is quite small, it is important that the "blank" correction for gases evolved from the crucible and furnace itself be low. Most of the "blank" gas originates in the crucible itself or at contacts between the hot crucible and any oxide refractories which may be present in the furnace for purposes of thermal insulation. The blank may be reduced to small proportions by proper furnace design and by preparation of the crucible by prolonged heating in vacuum at a temperature 300 to 500°C. hotter than that at which the analysis is conducted.

There are three methods of heating the crucible in use today. The first, and oldest, is the graphite spiral resistor furnace; the second is the high frequency induction furnace which was introduced by Jordan and Eckman² in 1925; the third is the graphite tube furnace recently described by Thanheiser.⁴ Descriptions of modern installations using each of the three methods will be found in the literature cited, references 8-17 inclusive.

The general method of conducting the analysis is as follows: Weighed samples, which must be solid pieces rather than drillings, are placed in the holder at the top of the furnace. The crucible is set up, the furnace closed, and pumps put into operation. The crucible is now brought to a temperature as high as the construction of the apparatus permits, representative figures from several laboratories ranging from 1750-2100°C. After heating for a half hour to two hours the temperature is dropped to that required for the analysis, 1550-1700°C. The pressure and rate of evolution of gas from the crucible are determined and used in computing the "blank".

The sample is dropped into the crucible and heating and pumping are continued until the pressure has returned to its former value; the time required here is from five minutes to two hours, depending upon details of construction and the type of steel analyzed.

The gases evolved may be pumped up to atmospheric pressure and transferred to an apparatus of the Orsat type for analysis or they may be analyzed by one of the simplified low pressure absorption methods described in several of the appended references.

The three chief sources of error in the vacuum fusion method are spattering of metal from the crucible, absorption of the gases by films of volatile metals which may form in the cooler parts of the furnaces, and incomplete reduction of refractory oxides. Trouble encountered in spattering may be overcome by melting samples with high oxygen content slowly under reduced temperature.

Hessenbruch and Oberhoffer³ noted deposits of manganese and aluminum on the walls of the furnace, and attributed low recoveries of oxygen from samples containing high percentages of these elements to the absorption of CO by the finely divided

metallic deposit. Vacher and Jordan⁹ reported the maximum allowable amounts of manganese and aluminum in the samples to be 0.24 and 0.05%, respectively, but Ericson and Benedicks¹⁰ who were the first to use wide, short connections between furnace and pump, placed the limits for manganese and aluminum at 3 and 2%, respectively. No limits for these elements can be accurately placed since the degree of their influence seems to be a function of the particular furnace in question. The influence of these elements is responsible for the move toward higher speed pumps and short, wide connections, since swift removal of the gases seems to cut down this effect by removing the gases before an appreciable film is formed. Other active volatile metals, such as calcium and barium, though rarely present, act in the same way. Thus, the calcium contained in ferrosilicon prevents the determination of oxygen in that alloy.

It has been shown repeatedly that at temperatures over 1550°C. all of the common oxides are completely reduced provided they are in a fine state of subdivision, such as the normal oxide inclusions in steel. When larger lumps of oxide are present, reduction is slow and in certain cases this constitutes a serious source of error.

The method has been applied to many types of plain carbon and alloy steels. It has found its greatest usefulness in the study of steel making methods rather than as a means of inspection of the finished product.

Fractional Vacuum-Fusion Method—Of the various methods now employed for the determination of oxides and gases in ferrous materials the fractional vacuum fusion method yields the most information, for the time involved. The technique and apparatus employed in this method of hot extraction, and the results obtained have been described by Reeve,¹¹ and amplified by Hoyt and Schell.¹² The method is applicable to the study of such materials as rimming, semirimming, and killed carbon steels, certain alloy steels, and cast iron.

The apparatus employed for the fractional method is essentially that used for the "total" oxygen method. The gases from each temperature fraction are collected at atmospheric pressure and analyzed separately by the usual methods of gas analysis. An improvement recently reported by Motok¹³ is extension of the height of the furnace to prevent condensation of metallic tin vapors on the window. This allows more than one analysis to be made without breaking the vacuum in the furnace.

The procedure is essentially as follows: The graphite crucible is outgassed at a high temperature to give a low blank correction which is as essential to the accuracy of this method as it is to that of the "total" oxygen method. After outgassing, the temperature is lowered to about 1550°C. and the amount of tin necessary to completely fuse the ferrous sample is dropped. The tin is allowed to degas before the temperature is lowered to 1000°C. and the base pressure determined. The weighed sample of ferrous material is then dropped into the bath of tin-carbon and the oxides FeO, MnO, SiO₂, and Al₂O₃ (and the gases nitrogen and hydrogen), are separated by a series of temperature fractions at 1050, 1170, 1320, and 1570°C.

The hypothesis concerning fractionation is that since simple oxides such as FeO, MnO, and SiO₂ will react with carbon at progressively increasing temperatures to give up their oxygen, then these oxides will react similarly when present as complex oxides or silicates in ferrous materials. It is likewise assumed that during the time of fractionation, the various oxides retain their own individuality, and that there is no displacement of equilibria to produce interaction between the oxides themselves or with metals such as Fe, Si, and Al which may be present in the sample.

One of the most important sources of error in vacuum fusion methods is the interference from metallic vapors of manganese or aluminum, which are distilled from the molten sample, and which react with carbon monoxide and lead to low recoveries of oxygen. The removal of the evolved gases at high speeds, the avoidance of drastic cooling of the furnace tube,¹⁴ and the use of a fresh graphite crucible⁹ for each determination on high manganese or aluminum killed steels have helped to give normal oxygen determinations for such samples. Furthermore, it has been found¹⁵ that the presence of tin assists in the recovery of oxygen from a high manganese steel. About half of the tin used in this method volatilizes during fractionation and presumably alloys with the metal vapors and lowers their reactivity with CO.

The chief advantage of the fractional vacuum fusion method as compared to the "total" oxygen determination is that knowledge of the distribution of the oxygen content of ferrous materials is obtained. This method allows the separate determination of specific oxides such as FeO, MnO, SiO₂, and Al₂O₃. Other oxides such

as those of chromium, vanadium, and titanium have been found to react at specific temperatures and in some instances have been separately determined. The total of the separately determined oxides is within the limits for total oxygen as determined by the vacuum fusion method.¹

The principal disadvantage of the fractional method, aside from the original cost of the equipment, is the length of time consumed in a determination. The separation of FeO and MnO requires close temperature control and frequent careful pressure readings. Samples high in FeO, especially when the FeO inclusions are massive, require longer dissociation periods, but, on the average, each fraction requires about 30 min. Observation of the time required to complete dissociation of the oxides at the different fraction temperatures may be advantageous at times because it gives the operator an indication of the particle size. The time required to analyze the gases from each fraction in a Type A—Orsat apparatus is between 20 and 30 min.

The following recommendations are offered, for efficient operation of the fractional method: (a) The sample size should be as large as possible to secure greater accuracy, the sample weight depending on the deoxidation treatment of the steel. For well deoxidized steel at least 50 g. of sample is desirable. (b) Substantially all blank gases, for all four fractions, should be eliminated by previous high temperature degassing and the use of a beryllia refractory shield around the graphite crucible. (c) C. P. stick tin with negligible gas content should be used. The amount of tin should be sufficient to completely fuse the ferrous material at 1000-1050°C.

Uncertainties of the fractional method for oxygen are as follows: (a) Reproducibility of results by different operators. Insufficient data are at hand to justify a statement. Check results on the same type of equipment by the same operator have been reported (Reeve, Scheil, Motok). (b) Completeness with which the oxygen from each fraction is extracted. Undoubtedly there is some slight overlapping. However, the results obtained by this method, both for FeO and MnO, are more in keeping with the melting practice and the inclusion content than are those of any other method.¹ There is some uncertainty regarding the complete reduction of alumina. (c) Error introduced by the upsetting of the equilibria. The equations

represent possible reactions but sufficient data are not available to determine the importance of these possible equilibria displacements. However, the remarks under item (b) of this paragraph also apply here.

Hydrogen Reduction Method—This method involves the passage of pure hydrogen over the sample heated to 1100-1200°C. for some selected period (usually between 1 and 2½ hr.), the H₂O, CO, and CO₂ being collected from the exit gases and their corresponding oxygen contents measured. General details of apparatus and method as used by various laboratories may be found in references 21-24 inclusive. Current procedures differ mainly in (a) form of sample and container, (b) method of heating, (c) elimination of surface oxygen, and (d) method of measuring CO and CO₂ in the exit gases.

The sample may be in lump form (10-20 g.) and melted, together with antimony^{21, 22} or antimony and tin, in a refractory boat in a horizontal tube furnace. There is evidence²⁴ that under these conditions, the true blank error is difficult to estimate because part of it (resulting from reduction of oxides in the containing boat or furnace tube) occurs only when the metal sample is present. The alternative method²⁴ is to use inductive heating and a sample* of thin millings in a degassed metal bucket suspended in a quartz bulb. Very low and accurately known blanks may be obtained, but the method brings its added complication in the surface oxygen on the thin millings. This surface oxygen, plus adsorbed oxygen or H₂O on the container and bulb surface is removed by heating all these parts in a resistance furnace at about 600°C., which lengthens the time for analysis and may cause the loss of a small portion of the contained oxygen in certain high oxygen samples. However, this latter method probably is more accurate and reproducible.

*In sampling rolled steel products of various forms, care should be taken that the pieces or chips used represent the average cross section perpendicular to the rolling direction, since such samples are often quite variable over this cross sectional area. This precaution should be common to all methods.

In the exit gases the percentage of the total oxygen present as H_2O varies from about 80-90% for low carbon samples, such as electrolytic iron or "low metalloid" steel, down to only 5-10% for medium and high carbon steels, the remainder being CO and CO_2 , which thus comprise the bulk of the oxygen from most steel samples. The H_2O portion is always collected in a P_2O_5 weighing tube, but the CO and CO_2 portions are collected either by (a) oxidizing the CO to CO_2 with a hot solution of iodine pentoxide and collecting CO_2 ,^{23, 24} or (b) by reducing both the CO and CO_2 to CH_4 and H_2O over a reduced nickel catalyst^{21, 24} and collecting the H_2O in a second P_2O_5 tube. A number of other methods of course are possible²¹ but the foregoing are favored in present practice. As to the accuracy of the iodine pentoxide method, the available data are really not adequate; the oxidation of CH_4 , which is nearly always present is one possible source of error in this method. The catalytic reduction method appears to give accurate results under optimum conditions. The nickel catalyst, in order to be active enough to give quantitative conversion to H_2O , must be reduced at such a low temperature that some residual nickel oxide is apparently always present. In addition to periodic checks on its activity, it must also be heated occasionally to 60 or 80° above its operating temperature (250-270°C.) for 6-10 hr. with hydrogen flowing, to maintain the desired accuracy.

Certain evidence²⁴ indicates that in ordinary steels, in addition to a fairly rapid recovery of dissolved oxygen and FeO, there is a much slower reduction of SiO_2 , MnO, and Cr_2O_3 , and possibly also of Al_2O_3 , TiO_2 , and other oxides when present in very fine particles. With 1.5-2.5 hr. of heating at 1100-1200°C., between 70 and 95% of the values obtained therefore represent dissolved and FeO oxygen, an absolute separation of the various forms of oxygen being impossible. Also, to obtain the most accurately comparable values, the conditions of time and temperature of reduction should be held constant for any group of samples.

Recent studies¹ show that we are still unable to give a reliable opinion as to the absolute accuracy of this, or indeed of any of the other methods for oxygen analysis in ordinary steels. Under optimum conditions it has been found²⁴ to give reproducible results to within 0.002% O₂ and has been useful in comparing samples made under similar conditions of manufacture. With some exceptions, the values obtained have not been found to be informative when different types of steel are compared as to oxygen contents. It would be especially doubtful to compare values on high silicon or chromium steels with carbon or low alloy steels. In general, however, the method can be used for nearly all types of low and high alloy steel, pure iron, and cast iron as well as nickel. The method can also be used for copper with a lower reduction temperature of around 950-1000°C.

The method requires between 2½ and 5 hr. for a single analysis. Skillful technique and a vacuum tight train are essential.

Iodine Method—When a sample of steel is treated with a suitable solution of iodine, the iron, silicon and manganese are dissolved and a residue of carbonaceous material (carbides in certain cases) and unattacked oxides remains.

In the procedure described by Cunningham and Price,²⁵ a sample weighing from 5-10 g. is treated at 3°-5°C. in a stoppered flask with an aqueous solution of iodine in ferrous iodide. After the sample has completely dissolved the solution is filtered and the insoluble residue is thoroughly washed to remove ferrous iodide, iodine, and other contaminants. The residue is then ignited, weighed and fused with sodium carbonate. The fusion is dissolved in hydrochloric acid and the SiO_2 , Al_2O_3 , MnO, and FeO contents of the solution are determined by the usual procedures of chemical analysis. It is claimed that sulphides and nitrides are decomposed by the ferrous iodide treatment and that the procedure is applicable to the analysis of plain carbon and manganese steels. Carbides of certain elements, for example chromium and vanadium, are not decomposed by the ferrous iodide treatment and, if present, lead to erroneous results in the determination of the oxide content of the residue.

In the procedure described by Rooney, Stevenson, and Raine,²⁶ the sample is treated with a solution of iodine in anhydrous methyl alcohol. Rather elaborate precautions are necessary to exclude moisture and oxygen from the solvent and containers while the steel is dissolving and during filtration of the resulting solution. After filtration and washing the residue is subjected to the usual procedure of chemical analysis for the determination of SiO_2 , FeO, Al_2O_3 , and MnO. Small amounts of Cr_2O_3 , ZrO_2 , and TiO_2 are sometimes found in the residues from plain carbon steels but these were probably present in the steel as carbides. The procedure suffers from interference by the presence of alloying elements of the carbide forming type and further work remains to be done to determine the role of sulphides and phosphides.

Willems²⁷ recommended the use of a solution of iodine in absolute ethyl alcohol and subsequent filtration through an ultra filter.

The principal advantages of the iodine method are the relatively low operation cost and the identification of individual oxides in the residue. On the other hand, the method is relatively slow, the analyst must be highly skilled in the difficult and complicated procedure, and the effect of carbides, sulphides and phosphides should be further studied. The results of the co-operative analysis showed that the aqueous iodine method in the hands of a skilled operator is accurate for the analysis of aluminum killed steels and of some silicon killed steels but that low recoveries of oxygen and oxides are obtained from other silicon killed steels and from rimming steels. Satisfactory concordance in the results obtained by different operators using the iodine method, particularly for the determination of FeO, is not yet attainable.

Electrolytic Method—The principle of the electrolytic method of oxide extraction is the same as the chemical solution method in that the metallic constituents are separated from the nonmetallics, and the oxides are determined in the residue. The sample is the anode of the cell, and the electrolyte should decompose all non-metallics except the oxides.

The study of methods for electrolytic extraction of oxides started with the publication, in 1929, of a paper by C. H. Herty, Jr.²⁸ concerning the theoretical aspects of obtaining the oxide residue from steel by electrolysis. Most of the research has been to find a suitable electrolyte, which must be neutral, have no solubility for MnO and manganese silicates or aluminates, and have an anion whose decomposition potential is lower than that of oxygen. This latter qualification is important as any formation of oxygen at the anode will cause serious contamination of the oxide residue. Also the anion must completely decompose other nonmetallics. Of all the anions considered, iodine has the greatest possibility of successful application.

Fitterer²⁹ in 1931 described an electrolytic method for the analysis of both oxides and sulphides using a solution of ferrous sulphate and sodium chloride for the electrolyte. Iron oxide could not be determined because of the voluminous precipitate of iron hydroxide during the electrolysis. Recent work by this method, on silicon treated carbon steels shows that the oxide residue contains silicic acid and carbides. Also the heat treatment of the sample affects the results.

In 1932, Treje and Benedicks³⁰ proposed the use of an electrolyte of sodium citrate and potassium bromide for oxide and sulphide extraction. This method was to be used on low carbon steel or iron as carbides were not decomposed. Apparently the sulphides were not quantitatively recovered and the residue contained silicic acid, metallics and carbides. Since the electrolyte increased in acidity during the electrolysis, only a small sample could be extracted before serious attack upon the oxide residue began.

In 1933, Styri³¹ described the use of an acid electrolyte for the extraction of oxides and sulphides. He found that the residue contained sulphides and carbides and some metallics. With the proper control of acidity, and heat treatment of the specimen to bring the carbon into solution, the method offered some promise for sulphides, silica, and alumina.

In 1932, Scott³² described an electrolytic method, with a magnesium iodide electrolyte, which combined the desirable features of the iodine solution method with those of electrolytic extraction. Using slags taken from "rimming" steel ingots, that were rich in manganous oxides and manganese-rich silicates, he determined that the recovery of the manganese compounds was high; over 80% for pure manganous oxides and 100% for silicon treated steels. Subsequent work demonstrated that all sulphides, phosphides, and carbides were completely decomposed, and with proper treatment of the residue, no contamination resulted from silicic acid.

Magnesium iodide as an electrolyte has many desirable properties. It is highly ionized, with resulting high conductivity. A fresh solution has a pH value of 8.5 which drops to approximately 5.3 after 200 hr. electrolysis. No oxygen is evolved at the anode as iodine has a decomposition potential considerably lower than oxygen. Hydrogen is evolved at the cathode, and magnesium is precipitated as the hydroxide, necessitating the addition of more magnesium iodide at intervals of 100-200 hr. The plating properties of the solution are good, and metallic iron and manganese are plated out, keeping their concentration low in the electrolyte.

High carbon steels and irons may be extracted with as great accuracy as low or medium carbon steels. If the specimen is difficult to decompose iodine plates out on the sample, combining the electrolytic effect with the solution principle by increasing the iodine concentration near the sample. The resulting rate of reaction

is slower, but the completeness of the reaction is unimpaired. In a recent paper³³ Hare and Soler reported that the method is applicable not only to all carbon steels but to nickel steels, low molybdenum, and certain low chromium steels. Joseph³⁴ described the application of the method to the determination of oxides in basic pig iron. Nearly 900 samples were extracted and analyzed over a period of about 9 months, with two men operating 12 cells.

The treatment and washing of the residue is of utmost importance after the extraction, and before the analysis. A complete description of the washing and an outline of the analytical procedure has been published in the paper by Joseph.³⁴ As carbon has the property of absorbing large quantities of salts, complete washing can only be accomplished by digesting the residue in the described manner, and thorough washing. These comments on the importance of complete washing and proper selection of analytical procedure apply to all residue methods.

Chlorine Method—If a sample of steel is heated at moderately elevated temperature in a stream of purified chlorine, the metallic constituents are converted to chlorides which are largely volatile under these conditions. The oxide constituents are not attacked by the chlorine and may be determined by suitable means in the residue from the chlorination treatment.

Procedures for the chlorine method have been described recently by Dickens,³⁵ Meissner,³⁶ Wasmuht,³⁷ Klinger and Fucke,³⁸ and Colbeck, Craven, and Murray.³⁹ Chlorination temperatures as low as 300°C. have been recommended on the grounds that some of the oxides are attacked by chlorine at higher temperatures, and have been criticized because of the difficulty of complete elimination of metallic constituents. Wasmuht reported that chlorination at temperatures of at least 500°C. was necessary for chromium, tungsten, and other alloy steels. Sufficient data are not yet available to define either the accuracy or the reproducibility of results by the chlorine method. It has been suggested that sulphides and phosphides probably do not interfere with the operation of the chlorine method, as they do in the iodine method.

Mercuric Chloride Method—In the mercuric chloride method, the sample is subjected to the action of an aqueous solution of mercuric chloride, 120 g. per liter. In the absence of air the reaction proceeds as follows:

Metallic iron thus goes into solution as ferrous chloride whereas FeO and MnO remain in the insoluble residue, from which they may be isolated or determined by suitable means. The determination of SiO₂ and Al₂O₃ is not attempted. The method was proposed by Maurer in 1909 and has been recently described in detail by Maurer, Klinger and Fucke.⁴⁰

Compounds of manganese and iron with phosphorus, sulphur, and nitrogen are not decomposed quantitatively. The presence in the insoluble residue of these compounds, or of metallic particles from incomplete decomposition of the sample, leads to high results for FeO and MnO. The limited number of determinations by the mercuric chloride method, that were reported in the cooperative analysis, showed that satisfactory results usually were obtained for MnO but that the results for FeO were consistently high. These data indicate that incomplete solution of the sample, resulting in the presence of metallic particles in the residue, is perhaps a more serious source of error than the presence of phosphide and sulphide compounds.

Nitric Acid Method—This method was developed by Dickenson⁴¹ and was thoroughly investigated by Herty and his associates.⁴² The method depends upon the solubility of metallic constituents and the relative insolubility of oxides, particularly alumina, in approximately 10% nitric acid.

Accurate results for Al₂O₃ are obtained by this method but the determination of SiO₂ is less satisfactory. There are two principal sources of error in the latter determination: (a) High results may be obtained because of the presence in the residue of hydrated silicic acid, formed during the solution of metallic silicides, and (b) Low results for SiO₂ may be caused by partial solubility of some of the silicates that occur in steel, particularly the less siliceous silicates.

FeO and MnO are quite soluble in dilute nitric acid and, therefore, are not determinable by this method.

Hydrochloric Acid Method—The use of dilute hydrochloric acid to effect the separation of metallic and nonmetallic constituents of steel was recommended by Kichline⁴³ for the determination of alumina. Additional data on the determination of silica as well as alumina were reported by Thompson and Acken.⁴⁴

The hydrochloric acid method yields accurate results for Al_2O_3 , but determinations of SiO_2 are less satisfactory. In the latter determination the chief sources of error are the presence of hydrated silicic acid in the residue and the partial solubility of certain silicates. The method is not applicable for the determination of FeO and MnO . The hydrochloric acid method resembles the nitric acid method in basic principles and in results obtained, but is preferable on the grounds of speed and simplicity of operation.

Methods for the Determination of Nitrogen—Nitrogen exists in ferrous materials chiefly in the form of metallic nitrides; the amounts of nitrogen that exist in solid solution or in the free state usually are of minor importance. In simple steels the nitrogen is present chiefly as iron nitride, but in modern steels, particularly alloy steels, other nitrides may be present in appreciable amounts.

Two procedures are in common use for the determination of nitrogen, the vacuum fusion and solution distillation procedures, and the results obtained by the two methods are usually in excellent agreement. Other methods that have been proposed for the determination of nitrogen include combustion in oxygen and fusion with sodium peroxide in a vacuum. In both methods nitrogen is recovered from the gaseous products of the reaction. The combustion method was described by Sawyer;⁴⁶ the method of fusion with sodium peroxide was proposed by Klinger.⁴⁷

In the vacuum fusion procedure, the conditions that produce reduction of the oxides likewise bring about decomposition of the nitrides, with liberation of elemental nitrogen which is collected and subsequently determined as the residual gas after absorption of carbon oxides and water vapor. All of the nitrides present in simple steels are readily decomposed, but Thompson and Hamilton⁴⁸ observed that the nitrides present in a nitriding steel (1.3 Cr, 0.16 Mo, 1.06 Al) were decomposed slowly.

As a result of his extended study of the fractional vacuum fusion method, Scheil believes that nitrides as well as oxides are fractionated by this procedure. This suggests that the various nitrogen fractions represent different combinations of nitrogen with other elements in the steel, although the nitrogen compounds may be present to some extent in solution or combination with the respective oxides and are released only when the oxides are reduced.

The solution distillation method for the determination of nitrogen depends upon the fact that when a steel sample, in the form of drillings or millings, is dissolved in hydrochloric acid the nitrogen of the metallic nitrides is converted to ammonium salts. If the solution is then made alkaline and boiled, these salts are decomposed with the liberation of ammonia. Determination of the amount of ammonia distilled from the solution furnishes a measure of the nitride nitrogen present in the steel sample. The procedure was originated by Allen,⁴⁹ in 1880. Jordan and Swindells⁵⁰ traced the development of the method and introduced improvements in the determination of the distilled ammonia and in the use of block tin in place of glass condensers to make the blank correction smaller and more uniform. Scott⁵¹ advocated the use of the iodide-iodate reaction, to avoid difficulty in the titration of the distilled ammonia.

In the early work with the solution distillation method it was assumed that all metallic nitrides were decomposed either by the hydrochloric acid or by the subsequent action of the sodium hydroxide solution. This assumption was permissible for simple steels, but it was now evident that modern alloy steels contain nitrides that are not decomposed by the simple Allen procedure. Johnson⁵² reported that the nitrides of V, Ti, Nb, and Zr were not completely decomposed in the ordinary procedure of solution in hydrochloric acid but were decomposed by a boiling mixture of perchloric and concentrated sulphuric acids. Subsequent work has shown that a combination of perchloric and hydrochloric acids is equally efficient.

The procedure now in use in Johnson's laboratory, for the determination of nitrogen in chromium metal, ferrochromium, chromium-nickel-molybdenum carbide steels, and plain carbon steels is, briefly, as follows:

The size of the sample, drillings or fine powder, varies from 1-5 g. or more depending on the nitrogen content. Place the weighed sample in a 600 ml. beaker, add 60 ml. of 1:1 HCl , cover, and digest on a hot plate, but do not boil. After solution of the sample is complete and evolution of hydrogen has ceased, boil the solution to reduce its volume to about 35 ml. Remove from the hot plate, add 60 ml. of 60% C. P. perchloric acid. Heat to heavy fumes of HClO_4 and continue fuming until the volume is reduced to about 20 ml. Allow beaker and contents to cool, add 200 ml. H_2O , boil 20 min. to dissolve all salts and allow to cool.

Subsequent steps in the determination are as described in detail in the article

previously cited.²³ The solution is transferred to a Kjeldahl flask, made alkaline, and boiled. The evolved ammonia is collected in a known volume of standard acid. Titration with standard NaOH, using alizarine for an indicator, furnishes a measure of the amount of NH_4OH in the distillate and hence of the amount of nitrogen in the steel sample.

The accuracy of the HCl-HClO_4 procedure has been demonstrated by comparison with results obtained by the vacuum fusion method and by an acid solution method in which sulphuric acid was used instead of the HCl-HClO_4 solvent. For many steels the results of all three procedures are in excellent agreement; for some materials, for example high carbon ferrochromium, the solution distillation methods yielded somewhat higher values for nitrogen than were indicated by a vacuum fusion determination. The HCl-HClO_4 treatment is definitely preferable to the H_2SO_4 procedure for the analysis of steels that contain insoluble carbides.

Methods for the Determination of Hydrogen—The vacuum fusion procedure is generally employed for the determination of the small amounts (usually less than 0.001%) of hydrogen that exists in ferrous materials.

In the vacuum fusion procedure, which was described in detail in the section devoted to the determination of oxygen, the hydrogen present in the sample is liberated together with nitrogen, from decomposition of the nitrides, and carbon monoxide from reduction of the oxides. The carbon monoxide and hydrogen are oxidized to CO_2 and H_2O respectively and the oxidized gases are absorbed separately. The gain in weight of the absorbent for H_2O , or the decrease in volume or pressure of the gas mixture as a result of the absorption of H_2O vapor, furnishes a measure of the amount of H_2O and hence of the amount of hydrogen evolved from the sample.

Schell has observed that hydrogen as well as nitrogen and oxygen is fractionated in the fractional vacuum fusion procedure and the total of the hydrogen fractions is usually higher than that obtained in the nonfractional procedure. As yet no satisfactory explanation of these observations has been offered but it has been suggested that the presence of tin may favor the evolution of hydrogen, perhaps by decreasing its solubility in the steel. Körber and Ploum²⁴ considered that the hydrogen evolved in a vacuum extraction at 400°C . was diffusible hydrogen whereas the hydrogen evolved at higher temperatures was present in the steel in a combined form. In general, steels charged with hydrogen evolved appreciable quantities of gas at 400°C . and smaller amounts at higher temperatures whereas normal steels, not specially charged with hydrogen, evolved little or no gas at 400°C . but did evolve hydrogen when heated to approximately 1000°C . This evidence indicates the existence of metal hydrides in steel.

Etching Reagents for Microscopic Examination of Steels and Irons*

(Only reagents of high analytical purity should be used.)

I. General Reagents for Irons and Steels (Carbon, Low and Medium Alloy Steels)

No.	Etching Reagent	Composition	Uses	Remarks
1.	Nitric acid (Nital)	Nitric acid, sp.gr. 1.42 1.5 ml. Ethyl or methyl alcohol, 95% or absolute 100 ml. (also amyl alcohol)	In carbon steels (1) to darken pearlite and give contrast between pearlite colonies; (2) to reveal ferrite boundaries; (3) to differentiate ferrite from martensite.	Etching rate is increased, selectively decreased, with increasing percentages of HNO ₃ . Reagent 2 (picric acid) usually superior. 4% in amyl alcohol useful for grain boundary and contrast of low carbon materials. Etching time, a few seconds to a minute.
2.	Picric acid (Picral)	Picric acid..... 4 g. Ethyl or methyl alcohol, 95% or absolute 100 ml. (Use absolute alcohol only when acid contains 10% moisture or more.)	For all grades of carbon steels (1) annealed, (2) normalized, (3) quenched, (4) quenched and tempered, (5) spheroidized, (6) austempered. For all low alloy steels attacked by this reagent.	Superior to reagent No. 1 except for those specific uses listed thereunder. More dilute solutions occasionally useful. Does not reveal ferrite grain boundaries as readily as No. 1. Etching time a few seconds to a minute or more. See Reference 2.
3.	Hydrochloric and picric acids	Hydrochloric acid. 5 ml. Picric acid..... 1 g. Ethyl or methyl alcohol, 95% or absolute 100 ml.	For revealing the austenite grain size in quenched, and quenched and tempered, steels.	Best results are obtained when the martensite is tempered for 15 min. at 400-475°F.
4.	Chromic acid	Chromic acid..... 10 g. Water 100 ml.	For various structures except grain boundaries of ferrite. Attacks cementite very rapidly, austenite less rapidly, ferrite and iron phosphide very slowly if at all.	Used electrolytically, the specimen as anode, the cathode stainless steel or platinum, $\frac{3}{4}$ -1 in. apart; 6 volts usually used. Time of etching 30-90 sec. depending on specimen. M. Baeyertz, Trans., A.S.M., 1937, v. 25, p. 1185.
5.	Heat tinting	Heat only.	Pearlite first to pass through a given color, followed by ferrite; cementite less affected, iron phosphide still less. Especially useful for cast irons.	Clean, dry polished specimen heated face upon hot plate to 400-700°F. Time and temperature both have decided effects. Bath of sand or molten metal may be used. See Reference 1.

II. General Reagents for Alloy Steels (Stainless and High Speed Steels)

No.	Etching Reagent	Composition	Uses	Remarks
6.	Ferric chloride and hydrochloric acid	Ferric chloride... 5 g. Hydrochloric acid. 50 ml. Water 100 ml.	Structure of austenitic nickel steels.	
7.	Aqua Regia	Hydrochloric acid. 75 ml. Nitric acid 25 ml.	Structure of stainless steel.	Mixture should stand 24 hr. before using; used full strength for rapid work, but requires careful handling.
8.	Chrome Regia	Hydrochloric acid. 25 ml. Chromic acid, 10% water solution... 5-50 ml.	Heat treated 18-8 stainless steels.	Activity is controlled by amount of chromic acid.
9.	Ferric chloride and nitric acid	Saturated solution of ferric chloride in hydrochloric acid, to which a little nitric acid is added.	Structure of stainless steel.	Use full strength.

(Continued)

*Prepared by the Subcommittee on Etching Solutions for Iron and Steel. The membership of the subcommittee was as follows: G. T. Williams, Chairman; Miss M. Baeyertz, G. F. Comstock, O. E. Harder, L. F. Lottier, Miss M. Norton, H. S. Rawdon, J. R. Villella.

The assistance of Mr. A. L. Sanford is also acknowledged.

No.	Etching Reagent	Composition	Uses	Remarks
10.	Mixed acids in glycerol	A. Nitric acid.....10 ml. Hydrochloric acid20-30 ml. Glycerol20-30 ml. B. Nitric acid.... 10 ml. Hydrofluoric acid. 20 ml. Glycerol20-40 ml. C. Nitric acid.... 10 ml. Hydrochloric acid. 20 ml. Glycerol 20 ml. Hydrogen peroxide 10 ml.	Structure of iron-chromium base alloys, high speed steels, and austenitic manganese steel. Etches nickel-chromium alloys satisfactorily. Structure of high silicon alloys of the Duriron type. For etching iron-chromium nickel, iron-chromium manganese, and all other austenitic iron-chromium base alloys.	Warm specimen in water before etching. For best results use method of alternate polishing and etching. If given sufficient time, will etch totally austenitic alloys, but better results are obtained by using reagent 10-C. Amount of glycerol may be varied to suit metal. Amount of hydrochloric acid may be varied if reagent acts too rapidly or slowly. For best results employ method of alternate polishing and etching.
11.	Oxalic acid	Oxalic acid..... 10 g. Water100 ml.	For austenitic stainless steels and high nickel alloys. Carbides and general structure revealed depending on etching time.	Used electrolytically, the specimen as anode, the cathode stainless steel or platinum, about 1 in. apart; 6 volts usually used. Precipitated carbides in stainless steels may be revealed in 10-15 sec., the general structure in about 1 min. For study of carbides, 1.5-3 volts may be used, thus increasing the etching time and improving control of etch.
12.	Mixed acids and cupric chloride	Hydrochloric acid. 30 ml. Nitric acid..... 10 ml. Saturate with cupric chloride and let stand 20-30 min. before use.	For stainless alloys and others high in nickel or cobalt.	Apply by swabbing.
13.	Nitric and acetic acids	Nitric acid..... 30 ml. Acetic acid..... 20 ml.	For stainless alloys and others high in nickel or cobalt.	Apply by swabbing.
14.	Hydrochloric and nitric acids in alcohol	Hydrochloric acid. 10 ml. Nitric acid..... 3 ml. Methyl alcohol....100 ml.	To reveal the grain size of quenched, or quenched and tempered high speed steel.	Etch 2-10 min. Snyder and Graff, Metal Progress, 1938, v. 33, p. 377.
15.	Ferricyanide solution	Potassium ferricyanide 30 g. Potassium hydroxide 30 g. Water 60 ml.	To distinguish between ferrite and sigma phase in iron-chromium, iron-chromium-nickel, iron-chromium-manganese and related alloys. Colors sigma phase light blue, ferrite yellow.	Must be fresh. Use boiling. Burgess and Forger, A.I.M.E. Tech. Pub., April 1938.
16.	Cupric sulphate	Cupric sulphate... 4 g. Hydrochloric acid. 20 ml. Water 20 ml.	Structure of stainless steels.	Marble's reagent.
3.	Hydrochloric and picric acids	Hydrochloric acid. 5 ml. Picric acid..... 1 g. Ethyl or methyl alcohol, 95% or absolute100 ml.	For etching many steels of the iron-chromium, iron-chromium-nickel, and iron-chromium-manganese types.	Reference 2.

III. Phosphorus Segregation, Phosphides, and Strain Lines

No.	Etching Reagent	Composition	Uses	Remarks
17.	Cupric chloride	A. Cupric chloride 1 g. Magnesium chloride 4 g. Hydrochloric acid 1 ml. Water 20 ml. Alcohol, absolute...100 ml. B. Cupric chloride 5 g. Hydrochloric acid. 40 ml. Water 30 ml. Ethyl alcohol..... 25 ml.	For showing segregation of phosphorus or other elements in solid solution; copper tends to deposit first on areas lowest in phosphorus. To reveal strain lines and their microstructure, and precipitation hardening in steel.	Dissolve salts in least possible quantity of hot water. Etch for about 1 min. repeating if necessary. Stead's reagent. May be used cold. Etching time, about 10 sec. Fry's reagent.

(Continued)

No.	Etching Reagent	Composition	Uses	Remarks
18.	Sodium picrate, neutral	Sodium picrate... 1 g. Water100 ml. (Wash salt well with alcohol to remove excess acid or alkali)	Shows difference between phosphides and cementite; iron phosphide attacked, cementite unattacked.	Use boiling. Etching time 20 min.
19.	Chromic acid and heat tinting	Chromic acid..... 8 g. Water100 ml. Followed by heat tinting.	Distinguishes between iron phosphide and cementite in phosphide eutectic of cast iron; iron phosphide is colored darker.	Etch first in picric acid (No. 2) then for 1 min. in chromic acid; heat tint by heating face upon hot plate at about 500°F. for 1 min.

IV. Structure and Depth of Case of Nitrided Steels

No.	Etching Reagent	Composition	Uses	Remarks
20.	Cupric sulphate and cupric chloride	Cupric sulphate...1.25 g. Cupric chloride...2.50 g. Magnesium chloride 10 g. Hydrochloric acid. 2 ml. Water100 ml. Dilute above solution to 1000 ml. with 95% ethyl alcohol.	For showing total depth, structure, and various zones of nitrided chromium - vanadium steels and Nitralloy.	Proportions must be accurate. Etch by immersion to avoid confusing edge effects.
21.	Picric and nitric acids	4% picric acid (No. 2)10 parts 4% nitric acid (No. 1) 1 part	For depth of case and structure of Nitralloy.	Best results are obtained when the specimen is annealed in lead at 1475°F. before etching.
1.	Nitric acid (Nital)	Nitric acid..... 2 ml. Ethyl or methyl alcohol, 95% or absolute100 ml.	For structure and depth of case of nitrided steels.	
16.	Cupric sulphate	Cupric sulphate... 4 g. Hydrochloric acid. 20 ml. Water 20 ml.	Total depth of nitrided case.	Marble's reagent.

V. Carbides, Nitrides, Tungstides, and Their Differentiation

No.	Etching Reagent	Composition	Uses	Remarks
22.	Sodium picrate, alkaline	Picric acid..... 2 g. Sodium hydroxide 25 g. Water100 ml.	Colors cementite, but not carbides high in chromium; in tungsten steels, iron tungstide (Fe_3W) and iron tungsten carbide ($\text{Fe}_3\text{W}_2\text{C}$) are colored more rapidly than cementite, but tungsten carbide is unaffected; attacks sulphides. Delineates grain boundaries in hyper-eutectoid steels in slowly cooled condition.	Use boiling, 5-10 min., or preferably, electrolytically at room temperature; for the latter, specimen is anode, cathode is platinum or stainless steel; with 6 volts, about 40 sec. is usually sufficient.
23.	Hydrogen peroxide and sodium hydroxide	Hydrogen peroxide 10 ml. Sodium hydroxide 10% solution in water 20 ml.	Attacks and darkens iron tungstide in carbon-free iron tungsten alloys. When carbon is present this solution darkens the compound ($\text{FeW} + \text{WC}$?) in proportion to the amount of carbide present; tungsten carbide is darkened.	Must be fresh. Etching time 10-12 min.
24.	Ferricyanide solution	A. Potassium ferricyanide 1-4 g. Potassium hydroxide 10 g. Water100 ml.	Differentiates between carbides and nitrides; cementite is blackened, pearlite turned brown, and massive nitrides remain unchanged.	Must be freshly made; etch 15 min. in boiling solution.

(Continued)

No.	Etching Reagent	Composition	Uses	Remarks
24. (Continued)		B. Potassium ferricyanide 10 g. Potassium hydroxide 10 g. Water 100 ml.	Darkens carbide containing chromium, carbides and tungstides in tungsten and high speed steels. At room temperature colors ternary carbides ($\text{Fe}_3\text{W}_2\text{C}$ or $\text{Fe}_2\text{W}_6\text{C}$) in a few seconds, iron tungstide (Fe_3W_3) in several minutes, and barely colors cementite.	May be used cold, but preferably hot, should be freshly made, etching time 5-10 min. Murakami's reagent.
25. Sodium cyanide		Sodium cyanide... 10 g. Water 90 ml.	Darkens carbides without attacking austenite or grain boundaries.	Used electrolytically, the specimen as anode, cathode, similar material, about 1 in. apart; 6 volts (not less than 5). Etching time 5 min. or more. W.B. Arnes, Trans. A.S.M., 1936, v. 24, p. 701.
4. Chromic acid		Chromic acid..... 10 g. Water 100 ml.	Attacks carbides in stainless steels very rapidly, austenite less rapidly, and ferrite very slowly if at all. For various structure of stainless steels.	See solution No. 4 in Section I.
11. Oxalic acid		Oxalic acid..... 10 g. Water 100 ml.	To reveal carbides in stainless steels.	See No. 11 in Section II. If strongly etched general structure is revealed; therefore for study of carbides reduced voltage is used for etching, giving better control of etch.

Macro Etching of Iron and Steel*

Part I

General—Macro etching of iron and steel consists of subjecting the metal to the action of a reagent in order to bring out the structure for visual inspection. Macro etching implies, to many people, merely routine inspection; however, as shown in the tabulation below, macro etching is widely used for many purposes.

Preparation of Sample—The preparation of the surface of the test specimen is governed by the intensity of the action of the reagent employed. Weak etching solutions require polished surfaces. Those solutions of a strength to produce a deep attack do not require as much care in sample preparation.

Unless otherwise noted, the samples should be in a soft condition. When, however, hardened material is to be etched, great care should be exercised so that the metal is not affected by the heat of grinding or cutting.

The surface required for each reagent is designated under the heading "Remarks" by the letters A, B, or C. Type A represents a saw cut or machined surface; B average ground surface; and C, polished surface. When using Type A surface, consideration must be given to the type of steel. For the higher carbon steels and for tool steels in general a cleanly sawed disc will produce very good results. On the very soft steels, a machined surface not too coarsely cut or a sawed surface, rough ground to remove all traces of flowed metal is desirable.

The compilation of etching solutions for macro etching that follows has been largely taken from Berglund's "Metallographers' Handbook of Etching." In making this compilation, an effort has been made to list the reagents under an alphabetical arrangement of the purposes for which the

Fig. 1—Section of embrittled boiler drum. Etched in hydrochloric acid.

Fig. 2—A longitudinal section showing flow lines.

reagents are intended. Different conditions will be revealed in the same steel by etching with different solutions, and it is well to be familiar with each in order to correctly interpret the results.

*Prepared by the Subcommittee on Macro etching. The membership of the subcommittee was as follows: M. W. Dalrymple, Chairman; R. L. Dowdell, Adam Steever, G. V. Luerssen, J. H. Higgins, and M. G. Yatsevitch.

Solutions for Macro Etching

Purpose	Composition	Remarks	Uses
Blowholes	10% sulphuric acid in water.	Use cold on large sections for 24 hr. Surface B.	Shows blowholes, porosity, pipe, and inclusions.
Blowholes	50% hydrochloric acid in water.	Use at 160-175°F. for ½ hr. Surface A.	Shows blowholes, porosity, pipe, and inclusions.
Carburized case	5% solution of nitric acid in alcohol.	Etch at room temperature. Surface B.	Shows depth of carburized case.
Contrast	1 part iodine; 2 parts potassium iodide; and 10 parts water.	Use at room temperature. Surface B.	Produces contrast for photographing.
Cracks	5% solution of nitric acid in alcohol.	Etch at room temperature. Etches within ½ hr. Surface B.	Detects fatigue, service, hardening and grinding cracks.
Cracks	Hydrochloric acid.	Apply cold with swab.	Detects embrittlement cracks in steam boiler drum. (See Fig. 1.)
Cracks	50% hydrochloric acid in water.	Use at 160-175°F. for ½ hr. Surface B.	Detects fatigue, service, hardening, grinding, and internal cracks. If hardened, material should be softened prior to etching.
Cracks	Kerosene and whiting test.	Wash surface with kerosene. Wipe off. Paint with thin mixture of whiting and water. Let dry. Kerosene in cracks, if present, will discolor whiting. Surface B.	Detects fatigue, service, hardening and grinding cracks.
Cracks	120 g. copper ammonium chloride; 50 cc. concentrated hydrochloric acid, 1000 cc. water.	Etch first with a neutral solution to remove machine marks. Use cold for 20 min. to ½ hr. Surface B.	Produces a strong relief effect. Shows up dendrites and may indicate cracks.
Decarburization	5% nitric acid in alcohol.	Etch at room temperature. Surface C.	The decarburized areas will be light. Area not decarburized dark.
Defects	10% sulphuric acid in water.	Use cold on large sections for 24 hr. Surface B.	Shows porosity, pipe, blowholes, and inclusions.
Defects	50% hydrochloric acid in water.	Use at 160-175°F. for ½ hr. Surface A or B.	Shows porosity, pipe, blowholes, and inclusions.
Defects	2 parts concentrated sulphuric acid; 1 part concentrated hydrochloric acid, 3 parts water.	Use at 160-175°F. for at least ½ hr. Surface A.	Shows general structure and defects.
Dendrites	2 parts concentrated sulphuric acid, 1 part concentrated hydrochloric acid; 3 parts water.	Use at 160-175°F. for at least ½ hr. Surface A.	Shows general dendritic structure and defects.
Dendrites	50% hydrochloric acid in water.	Use at 160-175°F. for at least ½ hr. Surface A.	Shows general dendritic structure and defects.
Dendritic pattern	25% sulphuric acid in water.	Use cold, 8-16 hr. Surface B.	Shows dendritic pattern and flow lines.
Dendritic pattern	40 g. ferric chloride; 3 g. cupric chloride; 40 cc. hydrochloric acid; 500 cc. water.	Etch first with 10% nitric acid. Surface B.	Shows dendritic pattern or structure.
Etch, universal...	500 cc. hydrochloric acid; 70 cc. sulphuric acid; 180 cc. water.	Use at 160-175°F. for 1-2 hr. Surface A.	Good universal etch.
Fiber	10-20% solution of ammonium persulphate in water.	Swab on freshly made solution for ½ min. Surface B.	Shows fiber and grain contrast.
Flow lines	25% sulphuric acid in water.	Use cold, 8-16 hr. Surface B.	Shows flow lines and dendritic pattern.
Flow lines	50% hydrochloric acid in water.	Use at 160-175°F. Surface A.	Shows flow lines.
Ghost lines	10-20% solution of ammonium persulphate in water.	Swab on freshly made solution for ½ min. Surface C.	Shows ghost lines.

Purpose	Composition	Remarks	Uses
Grain contrast	10-20% solution ammonium persulphate in water.	Swab on freshly made solution for 1-2 min. Surface B.	Shows grain contrast and fiber.
Grain contrast	1.5 g. cupric chloride; 30 cc. hydrochloric acid; 95 cc. water; 30 cc. ethyl alcohol.	Polish specimen carefully. Surface C.	Shows good grain contrast.
Grain size	10-20% solution ammonium persulphate in water.	Swab on freshly made solution for 1-2 min. Surface B.	Shows grain size especially in low carbon steels, wrought iron, and welded sections.
Hardness penetration	5% nitric acid in alcohol.	Etch at room temperature on smooth ground surface. Surface B.	Shows depth of hardness penetration of heat treated samples.
Hardness penetration	50% hydrochloric acid in water.	Use at 160-175°F. for about 15-60 sec. To preserve surface after etching, scrub in running water, dip in weak NH_4OH , dip in solution of soluble cutting oil, dry with a rag and compressed air. Surface B or C.	Shows depth of hardening, especially carbon steels; produces distinct contrast between martensitic and troostitic zones.
Heterogeneity	50% hydrochloric acid in water.	Immerse specimen in solution at 160-175°F. from 1/4-1 hr. Surface A.	Shows heterogeneity in general.
Heterogeneity	Undiluted hydrochloric acid.	Use hot (212°F.) Surface A.	Shows heterogeneity in 3-3.5% nickel steels.
Impurities in ferrite	1 g. cupric chloride; 0.5 g. stannous chloride; 30 g. ferric chloride; 30 cc. hydrochloric acid; 500 cc. distilled water; 500 cc. ethyl alcohol.	Etch only well polished surface which has been thoroughly dried. Surface C.	Plates out copper on ferrite containing impurities. Gives a good even etch.
Internal cracks...	50% hydrochloric acid in water.	Use at 160-175°F. for 1/4 hr. or longer. Surface B.	Shows internal cracks or thermal checks.
Inclusions	10% sulphuric acid in water.	Use cold on large sections for 24 hr. Surface B.	Shows inclusions, porosity, pipe, and blowholes.
Inclusions	10-20% sulphuric acid in water.	Use at 160-175°F. Surface B.	Etches sulphide inclusions.
Inclusions	50% hydrochloric acid in water.	Use at 160-175°F. Surface B.	Etches sulphide inclusions.
Pipe and porosity	10% sulphuric acid in water.	Use cold on large sections for 24 hr. Surface B.	Shows pipe, porosity, blowholes, and inclusions.
Pipe and porosity	50% hydrochloric acid in water.	Use at 160-175°F. Surface B.	Shows pipe, porosity, blowholes, and inclusions.
Rail sections.....	9 parts hydrochloric acid; 3 parts sulphuric; 1 part water.	Use at 160-175°F. for 2 hr. Surface A.	Use for etching rail sections.
Segregation	3% solution picric acid in ethyl alcohol.	Etch at room temperature for 4-5 hr. Surface B.	Shows segregation.
Segregation	1 g. picric acid; 1 drop concentrated hydrochloric acid in 25 cc. alcohol.	Use hot. Surface B.	Shows segregation.
Segregation	10-15% solution of nitric acid in water or alcohol.	Etch at room temperature. Surface B.	Shows heavy segregation.
Segregation	5% solution nitric acid in water or alcohol.	Etches within 1/4 hr. Surface is black when etched. Surface B.	Shows segregation in low carbon, low chromium, nickel steels.
Segregation	2-10% solution nitric acid in water.	Etch first with weak acid to remove machine marks and then increase concentration for structure. Surface B.	Shows segregation in ingot sections and large pieces.

Purpose	Composition	Remarks	Uses
Segregation	50% hydrochloric acid in water.	Use at 160-175°F. Surface A.	Shows segregation in ingot sections and large pieces.
Segregation	1 g. cupric chloride; 0.5 g. picric acid; 1.5-2.5 cc. hydrochloric acid; 10 cc. water; 100 cc. ethyl alcohol.	May be used for electrolytic etching. Surface B.	Shows segregation.
Segregation, carbide	2% nitric acid in alcohol. For high speed steel, use 5% nitric acid in alcohol.	Use cold on a polished, longitudinal section. For high speed steel, etch until matrix is darkened. Surface C.	To detect carbide segregations, particularly in high speed steels.
Segregation, carbon and phosphorus	1 part copper ammonium chloride, 12 parts water.	Immerse finely ground, clean sample in solution for 1 min.; wash with water, and rub off copper. Surface C.	Shows phosphorus and carbon segregation.
Segregation, phosphorus	0.5% solution picric acid in water.	Etch at room temperature until staining occurs. Surface C.	Uneven staining represents phosphorus segregation.
Segregation, phosphorus	30 g. ferric chloride; 100 g. hydrochloric acid; 1 g. cupric chloride; 0.5 g. stannous chloride; 1000 cc. water.	Polish as for microscopic work, use etch cold for 10 sec. to 2 min. Surface C.	Shows phosphorus segregation.
Segregation, phosphorus	10 g. cupric chloride; 40 g. magnesium chloride; 20 cc. hydrochloric acid; 1000 cc. ethyl alcohol (Steads No. 1 reagent.)	Dissolve salts in small amount of hot water, then add alcohol. Apply solution to polished surface drop by drop. Surface C.	Areas not coated by copper show phosphorus segregation.
Segregation, phosphorus	5 g. cupric chloride; 4 g. magnesium chloride; 1 cc. hydrochloric acid; 20 cc. water; 100 cc. alcohol. (Steads No. 2.)	Etch for 1 min. Surface C	Shows phosphorus segregation.
Segregation, phosphorus	4 g. cupric chloride; 20 cc. hydrochloric acid; 40 cc. water; 20 cc. ethyl alcohol.	Polish specimen carefully. Surface C.	Shows phosphorus segregation
Segregation, phosphorus	1.5 g. cupric chloride; 5 g. nickel nitrate crystals; 6 g. ferric chloride; 12 cc. water.	Immerse specimen for 90 sec. or more. Surface C.	Shows phosphorus segregation.
Segregation, sulphur	Soak ordinary sensitized photographic silver bromide paper in a 2% solution of sulphuric acid in water. Apply emulsion side of paper to smooth ground, clean sample for a min. or two. Rinse paper, fix in hypo, wash thoroughly.	The brown pattern formed on the paper indicates the relative distribution of sulphides. The darker and heavier the marks, the more sulphur is indicated to be present. Surface B. Best results are obtained only on first or second prints made from a surface.	Shows the distribution of sulphur.
Segregation, sulphide inclusions	10-20% sulphuric acid in water.	Use at 160-175°F. Surface A.	Etches sulphide inclusions.
Soft spots.....	5% nitric acid in alcohol.	Etch at room temperature. Surface B.	Nondestructive test for hardened tools.
Soft spots.....	50% hydrochloric acid in water.	Use cold on ground surface. Surface B.	Shows soft spots.
Strains	90 g. cupric chloride; 120 cc. hydrochloric acid; 100 cc. water.	Copper does not precipitate with this etch. Heat specimen to 400-475°F. for ½ hr., then etch ground surface for 1-3 min. Rub with powdered cupric chloride, then rinse with alcohol. Surface B.	Shows strain lines.
Strains	6 g. cupric chloride; 6 g. ferric chloride; 10 cc. hydrochloric acid; 100 cc. ethyl alcohol.	Heat specimen to 400°F. and immerse ground surface. Surface B.	Shows strain lines.

Purpose	Composition	Remarks	Uses
Strauss test	3% cupric sulphate; 10% sulphuric acid; 87% distilled water.	Specimen $\frac{1}{2} \times 1 \times 4$ in. is sensitized by actual welding, or artificially by heating to 900-1300° F. (generally 1250° F.). Immersed in the boiling cupric sulphate solution for 72 hr. Specimen is then bent 180° around $\frac{1}{2}$ in. pin. Cracking indicates disintegration has taken place due to migration of carbides to grain boundaries. Surface B. (120° fine emery.)	To measure intergranular corrosion of 18-8 corrosion resisting steel.
Structure	25% nitric acid in water.	Etch at room temperature. Surface B.	Shows general structure.
Structure	50% hydrochloric acid in water.	Use at 160-175°F. for at least $\frac{1}{2}$ hr. Surface A.	Shows general structure and defects.
Structure	2 parts concentrated sulphuric acid; 1 part concentrated hydrochloric acid; 3 parts water.	Use at 160-175°F. for at least $\frac{1}{2}$ hr. Surface A.	Shows general structure and defects.
Thermal cracks	50% hydrochloric acid in water.	Use at 160-175°F. for $\frac{1}{2}$ hr. or longer. Surface B.	Shows thermal checks or internal cracks.
Weld examination	50% hydrochloric acid in water.	When testing large sections, the acid may be added by building a dam with paraffin wax around the part to be tested. Surface A.	For testing the soundness of welds.

The balance of the section on macro etching has been divided into several parts, each dealing somewhat in detail with some of the more important applications of macro etching.

Part II

Recommended Practice for a Standard Macro Etch Test for Routine Inspection of Iron and Steel

General—The macro etch test reveals readily and quickly many of the characteristics of steel, but in some instances, further examination by standard testing methods is required to evaluate them properly. The knowledge that a piece of steel is dendritic or contains metallic and nonmetallic segregates is not sufficient evidence in itself on which to base definite conclusions of the properties of the steel. There is real value in the macro etch test when used to separate materials which are obviously defective from those which are not. It is easily made, but requires experience and judgment to interpret the results.

Preparation of Sample—When it is desired to reveal the surface defects, such as seams, laps, and grinding checks, preparation of the sample is frequently unnecessary. If oil or grease is on the surface, it should be removed. Scale on the surface of the material will be removed by the acid, so that the surface defects will become visible, but in order to reveal the internal structure or defects, a section must be prepared by cutting through the metal at a point where inspection is desired. For best results, the samples to be etched should be in a soft condition.

The surface finish of the specimen depends on the etching solution used. A machined surface is recommended as the standard surface finish in this practice. A ground and polished surface is not necessary and in many instances a fairly smooth sawed cut is satisfactory. This latter statement is true for the higher carbon steels and for tool steels in general. On the very soft steels, a machined surface not too coarsely cut or a sawed surface, rough ground to remove all traces of flowed metal is desirable.

Etching Solution—A solution of one part commercial hydrochloric acid and one part water is recommended. This solution has the advantage that it can be heated without change in concentration. The fumes of this mixture are corrosive so that the work is best done under a hood. (A solution consisting of 38% hydrochloric acid, 12% sulphuric acid, and 50% water is finding some use and shows promising

results. It can be used in the same manner as the recommended hydrochloric acid solution. The apparent advantages appear to be a more sharply defined etched pattern and less susceptibility to rusting.)

It is not necessary to throw away the acid after each test, but for the best results a fresh solution should be used for each test.

For containers pyrex glass, porcelain dishes, or corrosion resisting metals can be used. Satisfactory results have been obtained with hydrochloric acid and particularly with sulphuric acid using a lead lined iron pan or wooden tank provided care is exercised in the application of heat. It is felt, however, that a wooden tank is the least satisfactory type of container and its use should be avoided if possible. For heating the solution the method which gives the best temperature control should be preferred.

Temperature of Acid—A temperature of 160°F. is recommended. This temperature gives a vigorous reaction and does not evaporate the solution too rapidly. If the temperature rises much above 175°F., the etching solution tends to lose its selectivity and a reaction with the entire surface occurs rather than at just the localized points of attack as is desired. On the other hand, a solution temperature below 160°F. will usually unnecessarily prolong the etching operation with little gain resulting. The temperature should be determined with a good thermometer.

It is recommended to first clean the specimens and then heat them in hot water to the same temperature as the acid. The specimens are then transferred to the acid bath, which has first been heated to the proper temperature. By so doing it is much easier to control the time element than if the specimens are put into cold acid and brought up to temperature with the solution, and also it is easier to duplicate conditions time after time.

Time of Etching—The time of etching will depend upon the type of steel to be etched. It is extremely important that the time be accurately determined. If the steel is not etched long enough, the sample will not give all of the information desired; if it is etched too long, some of the more delicate details will be masked by the general destruction of the surface.

When the specimens are in a soft condition, the etching periods given in Table I have been found to give good average results.

Washing and Preserving Specimens—After the sample is etched, it should be removed from the hot acid and washed under running water, and the "smut" deposited on the specimen should be removed by scrubbing with a stiff brush. Live steam is also an excellent method of washing etched work. The piece is first thoroughly rinsed and placed under the live steam nozzle. This results in rapid and complete drying with freedom from rust. For drying the specimen after washing, it can be blotted with a cloth or paper towel or dried with a blower.

As a simple means of avoiding rusting temporarily, the specimen may be rinsed in water to remove the acid, dipped in ammonia and washed in hot water. For longer preservation, after the specimen has been dried, it should be covered with a thin coat of transparent lacquer, or a film of oil which may be applied with the palm of the hand.

Rusting may be delayed temporarily and mild rusting may be removed by the application to a dried sample of a solution of 50-50 syrup of phosphoric acid to which a little sugar has been added. The excess solution applied may be blotted up with a cloth or paper towels. Caution is recommended in the use of this solution as it will roughen the hands and disintegrate cloth, if allowed to remain in contact an extended time.

Interpretation of Results—The results obtained on properly etched samples are of great value if correctly interpreted. Surface seams, internal cracks, and pipe are easily recognized. It is the improper interpretation of the evidences of segregation and dendritic structures as revealed by deep etching that furnishes the greatest possibility of expensive errors and the needless rejection of material. *It is not true, moreover, that every pit developed indicates the occurrence of an inclusion, since pitting may also occur as a result of acid attack around carbide particles.*

Cracks from Etching—Hardened or otherwise highly stressed steels should be sufficiently tempered before etching to prevent cracking, since otherwise sound steel may crack in the etching solution and thus lead to false conclusions (Fig. 10, page 655).

Grinding Cracks—Grinding cracks can be easily distinguished by the standard macro etch test and are usually identified by a pattern of some symmetry (Fig. 25,

page 658). Again it is emphasized that hardened pieces should be softened prior to hot etching.

Surface Cracks—Surface cracks as revealed by deep etching usually follow an irregular path and may result from improper handling during heating, forging, rolling, or during cooling from the finishing temperature. With heat treated material, surface cracks may be caused by improper treatment, by improper grinding after hardening, or by service stresses.

Seams—Seams in rolled material are of varying depth and usually extend in a straight path parallel to the direction of rolling. With forged material, seams generally follow the contour of the forging and the flow of the metal. The most detrimental result of the presence of seams is their tendency to start fatigue failures, or to open up into deep hardening cracks if the metal is heat treated. This detrimental effect is avoided if, in the manufacturing operations, the surface is machined to a sufficient depth to remove the seams.

Surface Appearance—Steels may etch with a comparatively smooth surface or with a highly rough or pitted surface, depending upon variables in manufacture, and composition. Therefore, a highly roughened surface is not necessarily detrimental (Fig. 11, page 655). It has been found that smoother surfaces can be obtained by adding several drops of organic inhibitor, namely, triamylamine, to the hot etching solution. Inclusions are then attacked in preference to the metal, thereby eliminating the general roughness and consequently producing better patterns.

Irregularity in pitting may usually be attributed to one or more of the defects given below. Certain manganese, oil hardening types are more readily attacked by the acid and are often decidedly roughened without in any way being defective.

Center Porosity—Porosity may be the result of an actual discontinuity within the metal, in which case it is probably more proper to classify the defect as a pipe. Usually, however, the porosity is of such a nature that it is not visible until the specimen has been subjected to the etch. This condition can be found in widely varying degrees and the question of whether the steel should or should not be used is one of experienced judgment (Fig. 12, page 655).

Pipes and Bursts—Pipes are internal cavities formed during ingot solidification and carried through the various manufacturing processes to the finished product. Pipe is invariably associated with segregated impurities which are deeply attacked by the etching reagent. Cavities in the center not associated with deeply attacked impurities are often mistaken for pipe but such cavities can usually be traced to bursts caused from improper handling of the steel during forging or rolling. Either of these defects should be visible after deep etching, and can generally be distinguished from each other by the degree of sponginess surrounding the defect. Piped material usually shows considerably more sponginess than burst material (See Fig. 13 and 14, page 655).

Unsound Steel—Numerous blow holes and nonmetallic inclusions visible as the result of the deep etch are usually indicative of both gases and oxides being distributed throughout the steel at the time casting (Fig. 15, page 655).

Nonmetallic Inclusions and Metallic Segregates—Nonmetallic inclusions usually appear as pits and must not be confused with pits occurring from the etching out of metallic segregates. When nonmetallic inclusions are suspected in highly alloyed steels which may contain metallic segregates, a comparison should be made of an annealed specimen and a hardened specimen etched alike. If the etching pits are the result of nonmetallic inclusions, they will appear similarly in both the annealed and hardened specimens; if they are the result of a metallic segregate they will differ.

Segregations are revealed by the severity of the acid attack on the affected areas. The segregations may occur at the center and be so deeply attacked after etching that they may appear as a pipe, or the segregation may be grouped in some fairly regular form about the center, depending on the shape of the ingot and the mechanical work that has been done upon it.

Segregation as revealed by macro etching is not always an indication of defective material. The segregation revealed by macro etching can be identified by examining a polished specimen under the microscope to determine if it is metallic segregation, crystalline arrangement, or a concentration of impurities. The microscopic identification of segregation may also be supplemented by chemical means; such as analysis of center drillings for carbon, phosphorus and sulphur, or by analysis of inclusions after chemical extraction of same.

Internal Cracks—Internal cracks, sometimes called flakes, cooling cracks, or thermal checks, can be detected by the macro etch test and their identity can be

verified by a fracture test of a hardened specimen on which they are revealed as brightly crystalline spots. These cracks are an actual discontinuity in the metal and, depending on their nature and distribution, may make the steel unfit for use unless they are removed by further hot reduction (Fig. 16, page 655).

Dendritic Pattern—Etching often reveals a dendritic structure which is the result of the crystallization characteristics of the ingot. Dendritic patterns are detected even in steel that has been subjected to repeated mechanical reduction. It has not been proven that dendritic patterns are associated with service failures, provided the material has been subjected to sufficient mechanical working and provided the segregation accompanying the dendritic formation is not in the form of nonmetallic inclusions which are incapable of dispersion.

In the formation of dendrite crystals, the intercrystalline material contains minute metallic segregations which are largely diffused into the crystals. However, when nonmetallic inclusions are thus segregated, they are incapable of diffusion. The use of the microscope is suggested in such cases to supplement the macro examination (Fig. 17, page 655).

Pattern Effect—Pattern effect is almost wholly the result of the crystallization of the ingot and generally results from that part of the bar which was the columnar structure of the ingot etching differently from that part which was the granular structure of the ingot. Should the steel contain considerable sulphide and silicate inclusions, then the area of contact between the columnar structure and the granular structure may be particularly noticeable. In the absence of large amounts of sulphides and silicates, the pattern effect probably is of no serious consequence (See Fig. 18, page 656).

Grain Size—While the deep etch test is of no definite value in determining grain size, nevertheless the manner in which many specimens etch may indicate something of the grain size. Generally the larger the grain, the coarser will be the appearance of the etched surface (Fig. 19, page 656).

Decarburization and Carburization—Generally the areas which have been either decarburized or carburized will etch differently from the remainder of the specimen, chief difference usually being one of color. Decarburized parts will appear lighter in color and carburized parts darker (Fig. 20 and 21, page 656).

If the section to be examined is small enough, it can be given a polished finish and then cold etched, say from 5 to 30 seconds, in nital (3% HNO₃—97% ethyl alcohol). This will generally result in excellent contrast and if the polish is good enough, the same sample can be examined microscopically as well as visually.

Part III

Etching to Determine Penetration of Hardness and Soft Spots—There is a contrast in color, after etching, between the hardened (case) and the unhardened (core) sections of a heat treated section of shallow hardening steel. Use of this characteristic is quite valuable in determining the depth to which a sample has hardened.

To properly show up the penetration of hardness, the sample should have a finish equivalent to that produced by polishing with #00 emery cloth, or finer. The sample can then be etched either in hot or in cold acid. If hot acid, the ground sample is dipped from 15-60 seconds in solution of 50% hydrochloric acid in water at 160-175°F. If it is desired to etch cold, the ground sample is etched from 5-10 minutes in a cold solution 10% nitric acid in water. On a polished surface, nital produces excellent results. After either method of etching, the sample should be thoroughly washed in warm water with a cloth or sponge, and then dried with an air blast. If it is desired to preserve the etched surface of the specimen, the procedure for this, as suggested in Part II, should be followed (Fig. 21, page 656).

Soft spots which so often result when hardening carbon or low alloy tool steels can generally be distinguished by either of the above mentioned macro etching methods. The soft spots invariably etch in relief and are not so dark in color as the harder surrounding areas (Fig. 24, page 658).

Part IV

Etching to Reveal Flow Lines—A longitudinal section when subjected to macro etching will show, to a greater or less degree, flow lines due to the elongation of structural constituents. These flow lines indicate the directions in which the steel was worked during rolling or forging and do not signify defective material (Fig. 2).

The longitudinal face on which it is desired to develop the flow lines should have a smooth surface, either machined or ground. The etching procedure is carried out in 50% hydrochloric acid in water at 160-175°F. in the same manner as outlined in Part II. The length of time required to develop flow lines is a variable, therefore it is necessary to inspect the piece from time to time while it is etching in order to determine when the etch has progressed far enough.

Occasionally a piece will be encountered on which it is difficult to develop flow lines. A suggested aid is to paint the etched surface of the piece with India ink, and then when dry to lightly rub the inked surface with fine emery cloth. This removes the ink from the high portions of the surface and leaves the "valleys" blackened, thus providing the necessary contrast needed to show up flow lines.

Etched surfaces showing flow lines can be preserved in the same manner as other etched surfaces as noted in Part II.

The Significance and Interpretation of Nonmetallic Inclusions in Steel*

Introduction—The inclusions under discussion are the solid, nonmetallic particles present in steel. Gas bubbles and separated carbides are not included. The solid inclusions are primarily oxides, silicates, and sulphides. Some nitrides are included in this category. Few, if any, inclusions are pure chemical compounds, practically all are complex mixtures.

Source of Inclusions—Inclusions may come from the solid products of necessary reactions of the refining process, this type being "natural" inclusions, and normally are quite small, since they are the ones that have not floated out while the steel was still molten or were precipitated during freezing. Accidental or adventitious inclusions are produced by such things as slag mechanically entangled in pouring, eroded nozzle material, pieces of runner bricks, or molding sand. These inclusions get into the steel so late that they do not have time to escape before the steel solidifies. The natural inclusions may be present as a separate phase in the melt at high temperatures, or may be thrown out of solution from the melt because of changing equilibrium conditions and solubility as the temperature falls and the steel freezes.

Effect of Inclusions in Steel—All steel contains some inclusions. Some steels contain many, and among these, the predominant inclusions may be of different types.

Since an absolutely clean steel is commercially unattainable, one must use steel with some inclusion content. Free machining steels with a large content of inclusions of a selected type (mostly sulphides) fill an extremely important place. It is probable that such steels have lowered endurance values and some designers frown on the use of free machining steels for parts to carry load involving impact or repeated stress. It is true, nevertheless, that some types of high sulphur steel have been used successfully in numerous applications where service conditions are severe, as for example, rifle barrels and certain auto parts.

Moore¹ states that dirty steel is unreliable. Moore and Kommers² made endurance tests on annealed screw stock. Some specimens withstood 60 million cycles at 28,000–29,000 psi., but one broke after some 3 million cycles at 25,000 psi.

McAdam,³ Mathews,⁴ and Haigh⁵ comment on low endurance values due to inclusions. It is evident that an inclusion of such shape, nature, and orientation to the applied stress that it will act as an important stress-raiser, analogous to a surface notch, may have a harmful effect, especially in dynamic loading.

Johnson⁶ made endurance tests on aircraft engine steels and found the values to vary inversely with the inclusion count. The small well scattered inclusions had a negligible effect whereas the long stringer type were potent in lowering endurance values.

In static tests the effect of inclusions depends especially on the orientation of the inclusion and the applied stress. A rounded inclusion in cast steel does not have a directional effect on ductility, but elongated ones in wrought steel may cause the transverse ductility to fall markedly below the longitudinal ductility, though the tensile and yield strengths are practically unaffected. Wrought iron, with its slag stringers, is a notable example of a metal with directional properties caused by inclusions.

Effect on Mechanical Properties—That inclusions never exert any harmful effect on mechanical properties is a thesis that could not be defended. It is often extremely difficult, however, to establish that inclusions are harmful. For example, the Joint Committee on Effect of Sulphur and Phosphorus in Steel⁷ carried out exhaustive tensile, shear impact, and endurance tests on rivet steel, with S varying from 0.03–0.18% and hence, in the higher S steels, with copious inclusions of the MnS type. The sum total of all these tests was that the properties of rivet steels were practically unaffected by the inclusion content, except in respect to notch bar impact values. These were, of course, soft plastic steels in which redistribution of

*Prepared by the Subcommittee on the Significance and Interpretation of Nonmetallic Inclusions. The membership of the subcommittee was as follows: Clyde E. Williams, Chairman; C. H. Herty, Jr., John Chipman, D. J. McAdam, Jr., Merrill Schell, C. E. Sims, E. C. Smith, S. F. Urban, A. L. Boegehold, H. W. Graham, J. B. Johnson, L. A. Lanning, B. M. Larsen, G. C. Riegel, Frank Scott, F. N. Speller, Haakon Styrl.

stress takes place readily. This may account for the minor effect of the MnS inclusions.

The distribution of inclusions may profoundly influence their effect on the mechanical properties of steel. This has been clearly demonstrated for cast steel by Sims² and Lillieqvist who showed that sulphide inclusions when present as widely separated globules had a minimum effect on ductility and notch bar impact values, but when they are strung out in the primary grain boundaries as films or eutectic formations, they may drastically lower these properties.

Certain Types of Inclusions May Be Beneficial—It is generally considered that a steel to which aluminum has been added for purposes of grain size control contains Al_2O_3 inclusions or complex inclusions largely made up of Al_2O_3 , even though we cannot see them under a microscope. Whether one wishes to consider Al_2O_3 or residual Al as the primary cause of inhibition of grain growth, few will dispute that Al_2O_3 is present. In this case, however, it is almost certainly the submicroscopic and not the visible particles which restrict the grain growth. Bain³ commented on the exaggerated grain growth and propensity toward hardening cracks of very pure Fe-C alloys and remarked that where it is necessary to handle such material commercially, one would have to add judiciously selected nonmetallic material to make it fit for service. On the other hand, clumps of Al_2O_3 , visible to the unaided eye are known to be deleterious to tool life in machining and to dies in wire drawing.

Nonmetallic particles of sufficient number and of submicroscopic size may have a marked strengthening effect on mechanical properties, but, especially if the matrix is ductile and if the particles are rounded, the same materials agglomerated to the size of the smaller inclusions that we can see under the microscope, have much less effect. This is evident in the difference in properties of two precipitation-hardening alloys, one of which is fully hardened and the other over aged so that the hardening particles were agglomerated.

Inclusion Rating Charts—For any particular service, between the unattainable lower limit of a steel with no inclusions at all and the upper limit of a steel so dirty as to be admittedly unsuitable, there is some not well defined region that divides the acceptable steels from the unacceptable. For a long time, producers and users have attempted to precisely define this region, and to find methods for definitely specifying the limiting content, size, type, and distribution of permissible inclusions.

These attempts usually take the form of "inclusion" charts or numerical ratings derived from the charts, showing unetched micrographs with characteristic inclusions as to size, shape and frequency of occurrence. The specimen, selected from a predetermined position in the bar or billet, is rated by the comparison with the chart. There is no unanimity in the standard charts, each large purchaser is likely to have his own, and each steel mill may, in addition, have its own chart. However, the charts do not vary enough to make it important which particular one should be adopted when the time comes to standardize some more official method of rating.

The difficulty in the use of any chart lies, not in telling what standard micrograph or micrographs match the inclusions in the specimen being examined, but in knowing that the specimen is a representative sample. A large number of sections must be examined in order to establish on a statistical basis what the correct rating of the steel may be. Apparent uniformity in the specimens examined, moreover, does not prove that the steel does not have some large or segregated inclusions in some other part of the heat. With sufficient patience almost any one who wished to reject a lot of steel could find some single field under the microscope containing sufficient inclusions to appear to justify a claim that the steel was not of proper quality, although this field might represent only the minutest area of the whole lot of steel under consideration.

By their very nature, inclusions are not homogeneously distributed through the steel, so that random sampling may entirely fail to appraise the steel as a whole.

Chance plays an important part in the distribution of inclusions, and likewise in the location of an inclusion at a point of crucial stress in an actual structure. For example, it is by no means uncommon, in examining a rotating beam endurance specimen which has shown normal life, to find a few hundredths of an inch away from the most highly stressed area of the surface, an inclusion which, had it lain in that most highly stressed area, would have led to early failure, but because it was not situated at the unfavorable location, did no harm whatever. Likewise, large inclusions elongated in the direction of the stress often have an insignificant effect.

Poor fillets, tool marks, key ways, stamped numbers, accidental scratches and

similar imposed stress-raisers, cause a thousand failures to one that is properly ascribable to a stress-raising inclusion in the metal itself. Yet, in some uses, such as automotive and aircraft ordnance, and in pressure vessel applications, it is important to eliminate the possibility of the one failure due to an inclusion.

One would expect a close correlation between inclusion content and performance in hard, highly stressed balls, rollers, and races of antifriction bearings. Steels containing large inclusions, visible to the naked eye on a polished surface, have been found to be subject to flaking and spalling, and many fatigue failures in large roller bearings have been definitely shown to have their origin in slag stringers so large that they must have been of accidental or adventitious origin. Little definite relation has been found between bearing life and presence of the normal inclusions of microscopic size. The opinion is held by some bearing manufacturers, nevertheless, that even small inclusions are harmful in very hard steels.

It is chiefly in the case of impact or repeated stress that the accidental stress-raising inclusion is to be feared in otherwise satisfactory material. The problems of directional ductility in deep drawing, cold bending, flanging and similar operations where breakage might occur in fabrication are easily handled by transverse bend and tensile tests in standard mechanical testing, and the inclusion problem is not of direct importance from the point of view of such fabrication. Inclusions might be the last straw to render material otherwise somewhat lacking in suitability obviously unsuitable, but will seldom indeed be a major cause. Steel for quenching may be more prone to quenching cracks because of inclusions, but this again is seldom a major cause of trouble, other factors usually being far more potent.

From the point of view of mechanical failure inclusions met in ordinary commercial steels may be said to have practically no deleterious effect in parts made of ductile material, subjected to static stress. Under applied stress such material is deformed plastically at the apex of the stress-raiser, the stress is redistributed, and nothing further happens. As the matrix becomes harder, through increase in carbon or alloy content, and still more markedly when hardened by excessive cold work or by quenching, followed by only a limited toughening by tempering, as in spring steel, the effect of an imposed stress-raiser is more marked, even in static loading, and still more marked in impact or under repeated stress. The effect of a stress-raising inclusion is analogous to that of an imposed stress-raiser. Hence, inclusions may be expected to have little effect in soft steels under static load, as in structural steel for buildings, but an important effect in very hard steels under dynamic loading.

To impose the same inclusion ratings on reinforcing bar and on airplane connecting rods would be poor engineering. Yet it is difficult for the engineer to determine the proper inclusion rating for an automobile gear steel, and wide differences of opinion exist.

Inclusions May Be Detrimental in Welds—In this case again it is the gross inclusions that are most feared. Slag reaction products have very little time to rise in the short time the weld metal is fluid. Welding rods coated with, or containing, materials that produce a blanket of reducing gas to exclude oxygen and nitrogen of the air, and others that produce very fluid slags with the oxygen contained in the air that reaches the weld, as well as processes of welding under layer of fluid slag, are employed to avoid weld defects arising from inclusions. These large inclusions are generally detectable by radiography so that specific inspection methods are available through which to trace down and eliminate the causes of trouble.

The suitability of steel for welding and for use in welding rods may be affected by gas evolution resulting from reaction of carbon with oxygen in oxide or silicate inclusions, which gas may cause splatter. Inclusions of MnS are reported to exhibit profound effects at the temperatures used in welding. Direct tests are, of course, available to handle such problems.

There are cases in which there is no fear of inclusions directly on the score of strength, but where they may nevertheless injure the suitability of steel. Objects that are given a high polish may have poor appearance due to the presence of large inclusions in the polished surface. In some instances embedded particles of the polishing medium have been mistaken for inclusions. Metal plated on a surface carrying inclusions may not adhere at the locations of the inclusions. Direct tests as to the specific effect may be applied in such cases.

The Effect of Inclusions on Corrosion Is in Dispute—It is alleged for wrought iron that the inclusions improve the corrosion resistance while in stainless steel they have been termed definitely harmful. There is not enough difference in the corrosion rate of wrought iron and mild steel to warrant the conclusion that the

presence of inclusions has any effect. As far as the great tonnage of steel is concerned, corrosion resistance is a secondary factor and inclusions cannot change its order of magnitude.

Sulphide inclusions on polished surfaces are sometimes thought to tend to localize corrosive attack. Most other inclusions are so resistant to solution by water that they appear quite inert in respect to either atmospheric or submerged corrosion. On the whole, normal variations in the corrosive environment have far more influence than variations in inclusion content.

The effect of inclusions on machinability and tool life is not very clear. Very clean steels, by the usual inclusion rating, may behave worse than a very dirty steel and the free cutting steels intentionally carry large amounts of sulphide, selenide or other relatively soft inclusions. It is not yet definitely settled as to whether these inclusions have a direct or corollary effect on machinability, and the speed at which such steels can be cut is not necessarily in the order of the amount of visible inclusions present. It may well be that inclusions of submicroscopic size have as much effect on machinability as larger ones. Steels so finished as to contain any free Al_2O_3 are not considered ideal for good tool life. Very large inclusions, even of softer materials, may cause the tool tip to chip.

Here again, specific tests, made under service conditions are better criteria than any ordinary inclusion rating.

General Considerations—Considering the inclusion problem as a whole, the very large, accidental inclusions of the type produced by eroded nozzle, runner brick or other foreign matter that gets into the steel so late that it is caught instead of rising out of the steel, are universally considered detrimental. It is an impossible task certainly to detect such an adventitious inclusion, since there might be but one in an ingot and every possible sample, other than that right at this inclusion, will give no hint of its presence. Avoidance by scrupulous cleanliness and adequate cropping, rather than testing, must be the remedy for such cases.

In general, any inclusion larger than the size corresponding to 0.01 inch diameter before the steel is worked, may be suspected of being adventitious.

The smaller natural inclusions tend to be more uniformly distributed through the steel, but segregation occurs during freezing, and this segregation is affected by many variables so that there is little assurance that a sample from any one location in the ingot will tell definitely the inclusion content at other locations.

The necessity for systematic sampling in making inclusion counts under the microscope has been stressed by Epstein.¹⁰ A random sample on a bar whose location in the ingot is not known stands little chance of appraising all the steel from that ingot and still less, all from that heat.

From the point of view of mechanical properties of steel containing inclusions, one is interested in the composition and nature, shape and distribution of the inclusions. This phase of the subject is discussed in other sections of the Handbook and may be referred to for details.

Inasmuch as the methods for determination of the inclusion rating of a steel are so difficult and time consuming, and generally so unreliable (because of defects in the methods and especially because of difficulties in sampling) it is not remarkable that few clear-cut conclusions can be drawn as to the exact effect of inclusions. It is plain that the most dangerous inclusions are the large ones that get in by accident, and that determination as to whether such inclusions exist in a given lot of steel is a difficult if not an impossible matter. The experience of industry, however, has indicated that within certain broad qualitative limits more consistent and uniform performance may be expected in dynamic service from those steels which contain a minimum of nonmetallic inclusions. This conclusion has led to a great amount of study and effort to produce cleaner steels and there is no doubt that this work has resulted in a lower average inclusion content for high grade steels.

It seems certain that nonmetallic inclusions have their greatest significance for the steel plant metallurgist, because they so often furnish excellent circumstantial evidence for the diagnosis of pathological conditions. This phase, of course, is more concerned with identification and distribution than with quantity and inasmuch as its ramifications lead deeply into the field of process metallurgy, it is outside the province of this article.

In regard to serviceability, the deleterious effect of the microscopic, normal inclusions of carefully made steel has probably been over emphasized. Some large users of steel for dynamic service consider the test for microcleanliness the least

significant of all the tests used for acceptance of steel. While it is true that inclusions have been identified as the direct or contributory cause of some failures, in most failures in service it is wise to look for other plausible causes for trouble, before worrying about the probable effect of an occasional inclusion.

Identification of Inclusions in Steel by the Use of Reflected Polarized Light*

Introduction—The use of reflected polarized light is a comparatively new tool in metallography. Transmitted polarized light has been used for some time to determine strain in transparent substances (photoelasticity). The use of polarized light to determine the constituents of mineralogical thin sections is well known and in technological practice. The science of mineralogy has thus far described 261 minerals as opaque, of which 93 are shown by the microscope to be either mixtures of minerals or doubtful species.¹ The use of a polarizing microscope is no longer confined to the field of petrography. Due to the pioneer work of Dr. Emile Chamot, the polarizing microscope is now used to advantage in the field of chemical microscopy.² Slag investigations have been carried out and the mineral composition determined with the aid of the polarizing microscope.^{3, 4} Research workers in various branches of science have given testimony to the possibilities of investigation with this tool. Although the use of polarized light was recommended for the study of opaque substances as early as 1909 by Königsberger,⁵ it has not been used in metallography until quite recently. A few treatises have appeared from time to time dealing with reflected polarized light in the study of opaque ores and metals (See references 6-18).

The use of reflected polarized light to identify opaque substances has not been as outstanding as the effects obtained with transparent materials. Until quite recently all of the polarizing microscopes for reflected light did not furnish truly linear but slightly elliptically polarized light in the plane of the object.⁶ The amount of this elliptical polarization was small but in some cases was sufficient to produce abnormal extinction effects. In recent years the vertical illuminator has been much improved in the homogenization of the field for observations between crossed nicols and improvements in this direction are being continued.^{7, 8}

During the past six to seven years efforts have been made by various investigators to apply polarized light to metallography, as a further means of identifying inclusions, structural components and phases. In the development of what is practically a new branch of science, it is not surprising that the results obtained by earlier investigators were not always in agreement. The investigations that have been reported show the utility of polarized light in the study of nonmetallic inclusions (See references 19-31).

During the evolution of this new tool, for metallographic investigation, research workers have realized that certain limitations must be placed upon its use in order to arrive at the correct interpretation of the results given. In order that the investigator shall not obtain an erroneous identification of the inclusions to be studied, he should have in mind these limitations before attempting to make full use of reflected polarized light. He should also realize that this method, of itself, is often not conclusive and therefore should be used with the aid of other methods of identification such as etching. The nature of the optical phenomena observed is dependent, to a significant extent, on the design of the optical system.

Polishing the Inclusions for Microscopic Examination—The preparation of the sample for the study of inclusions is of great importance to the success of the examination. There are several good methods of preparing the surface, and any method of polishing which gives the following results should be entirely satisfactory: (1) A smooth and level metal surface; (2) retention of inclusions; and (3) a satisfactory polish on the surface of the inclusions, free from scratches, distorted surface layers, and films.

The sample for examination of inclusions may be mounted in bakelite or hard resin to facilitate hand polishing or automatic polishing of small specimens. The usual preliminary polishing steps are employed, such as coarse grinding and fine grinding on the metallographic dry papers No. 1, 0, 00 and 000. Frequently, used 000 paper rubbed over with paraffin or graphite is employed. The use of graphite is cautioned against, at least for inexperienced polishers, as this practice frequently leads to embedded graphite in the surface layers of metal during polishing. Such embedded graphite, after final polishing with alumina or magnesia, may have the appearance of an inclusion.

*Prepared by a subcommittee, the membership of which was as follows: Merrill A. Scheil, Chairman; Mary Baeyerztz, and Joseph R. Vilella.

The final polishing is carried out on broadcloth laps using levigated alumina or magnesia. After final polishing it is important to properly clean and dry the prepared surface. Dried water spots produce bright areas under crossed nicols, and clumps of the polishing media or dirt tend to sparkle on the otherwise opaque polished surface, and may lead to erroneous conclusions. It is not advisable to etch the prepared polished surface before microexamination, with polarized light, because the surface roughness produced by etching causes scattering reflections which are confusing and may lead to grating polarization. Heat tinted specimens should not be used since such treatment may cause oxide films on the surface of the inclusions.

Method of Examination—After proper preparation of the polished surface the section is first thoroughly examined under ordinary reflected white light to determine the size, shape, color by ordinary reflected light, and distribution of the inclusions. The section is then examined with reflected plane polarized light with nicols crossed. Two determinations are made, namely, the determination of the color by transmitted light and the examination for evidence of anisotropic behavior.

Path of the Rays in Microscopes for Use With Reflected Plane Polarized Light—The examination of inclusions with reflected plane polarized light may be made with the usual types of metallurgical microscope, if accessory equipment with which to obtain and analyze the plane polarized light is added, and certain precautions are observed. Some manufacturers now make such equipment in holders especially designed to fit into the optical train of microscopes of their own manufacture.

The usual source of light for a metallurgical microscope is an arc or filament lamp. Light from either of these sources may be considered as vibrating in all directions normal to the light beam. In order to obtain plane polarized light (vibrating in one direction only), it is necessary to interpose a polarizer in the light beam. The polarizer should be situated between the light source and the field stop or aperture stop. The polarizer should always be protected by a heat absorbing glass placed between it and the light, in the case of an arc lamp. With small incandescent lamps this is not necessary.

The polarizer, commonly termed "nicol prism," is so constructed that when a beam of unpolarized light is passed into it, the resulting transmitted beam is plane polarized. The vibration direction of the light emerging from the polarizer can be regulated by rotating the polarizer around the axis of the optical train. The polarizer should be rotated until its vibration direction is either perpendicular or parallel to the axis of tilting of the reflector in the vertical illuminator and then be kept in that position during microscopic observations. If the polarizer deviates only a fraction of a degree from this position, elliptical polarization will be introduced.

From the vertical illuminator, usually a prism of special design, the plane polarized light is projected through the objective to the specimen surface from which it is reflected into the microscope to the eyepiece which forms the visible image. Before being viewed at the eyepiece, the light reflected from the specimen is passed through an analyser. The analyser may be placed between the vertical illuminator and the eyepiece or a cap nicol, placed over the eyepiece, may be used instead.

The analyser functions in a similar manner as the polarizer. Thus only plane polarized light which vibrates in the direction of the analyser can pass through it. When the vibration direction of the analyser is set at 90° to the vibration direction of the polarizer, the nicols are said to be "crossed." With crossed nicols the plane polarized light which passes the polarizer, if reflected unchanged to the analyser, cannot pass the analyser and the field of view is dark. If the character of the polarization is altered, that is, if the plane polarized light becomes elliptically polarized, or the vibration direction of the polarized light is changed then light will pass the analyser.

Change in the character of polarization and resolution into components of the vibration direction of plane polarized light can be caused by reflecting surfaces in the optical train, so it is advisable to eliminate them or place them so that the minimum effect is obtained. Rotation of the specimen should be obtained by rotating the stage on which the specimen is fixed. For this purpose the microscope should be equipped with a rotatable stage, preferably graduated in degrees. Cross haired eyepieces, representing planes of vibration of the nicols, are very desirable.

Brightness, Color, and Surface Anomalies—Brightness or transmitted light color may usually be observed in a few inclusions if a number are present and if the inclusions are transparent or reasonably translucent.

The transmitted light is observed because incident plane polarized light is refracted into and transmitted through the translucent inclusions and is reflected from the inclusion metal interface, from a crack in the inclusion upon which back reflections can take place, or, in inclusions which contain more than one phase, from the phase boundaries within the inclusion. The light coming out from the inclusion is no longer plane polarized as it was before entering the inclusion. Random reflections from the inclusion metal interface and other internal interfaces cause the character of original plane polarized light to be changed so that light passes the analyzer. This effect has no connection with anisotropism (both isotropic and anisotropic substances show it) and particular care should be taken not to confuse it with anisotropic behavior. If the nicols are parallel appearance of the inclusions is similar to that observed by ordinary reflected light. The general illumination from the incident beam as reflected from the polished metal surface is so great that the much weaker transmitted light from the inclusion cannot be observed or is seen only indistinctly. This small amount of light from the internal reflection through the inclusion may be seen by crossing the analyzer nicol, which efficiently removes the surface reflected light and if the inclusion is sufficiently translucent its transmitted color can be identified provided that the birefringence of the inclusion mineral is not high. Under certain conditions of internal reflection in minerals of high birefringence, the colors observed with crossed nicols are interference colors rather than the transmitted light color of the mineral. If the substance is translucent the transmitted light color may be complicated, with certain anisotropic inclusions, by reason of high absorption for certain wave lengths which vary in certain crystallographic directions of crystalline inclusions (reflection pleochroism).

Aside from these confusing effects in certain anisotropic inclusions, the determination of the transmitted light color depends on the following factors: (1) The dimensions of the inclusion; (2) the orientation of the reflecting surface with respect to the vibration planes of the nicols; (3) the translucence of the inclusion; (4) the method of polishing (freedom from polish film, scratches, and differences in level of different constituents); (5) the crystallographic orientation of any anisotropic crystals in the inclusion from which internal reflection takes place; and (6) the numerical aperture and type of objective.

Thus reflection through a relatively thin layer of a highly translucent substance from a metal inclusion interface or, in inclusions which contain more than one phase, from a highly reflecting phase-translucent phase interface will give the maximum reflected light for observation, provided that the reflecting surface is properly placed with respect to the vibration directions of the nicols. The difficulties of determination of the transmitted light color increase markedly as the translucence of the inclusions decreases. An objective of high numerical aperture sometimes alters the apparent brightness and color of the inclusion regardless of whether it is translucent or opaque. This is probably due to the fact that less of the plane polarized light can be reflected unchanged, because of the possibility of introducing elliptical polarization caused by objectives used for high magnification. The light gathering properties of the high numerical aperture lenses make any particular inclusion, only slightly translucent, appear brighter than with lower numerical aperture lenses. With opaque inclusions, especially, immersion objectives modify the apparent reflectivity. The apparent reflectivity increases as the difference between the refractive index of the inclusion and the refractive index of the surrounding material increases. Portevin and Castro⁸ have observed that examination under a dry objective generally gives more violet shaded colors than an immersion objective does. At times the dimensions of the inclusion and the surface polish offer disturbing effects to a proper identification. In certain hard inclusions of small dimensions, their surface is not always polished plane and is frequently convex. When examined by reflected polarized light, diffraction and depolarization phenomena are set up at the edge of the inclusion. Likewise, pits and scratches on isotropic surfaces improperly prepared can produce effects which may be mistaken for anisotropic behavior.

Anisotropic Behavior—Examination of the inclusions by reflected polarized light between crossed nicols may enable the investigator to distinguish the isotropic

vitreous (no crystal system) and crystalline substances (cubic system) from the anisotropic substances (all other crystalline systems).

Substances showing one index of refraction are called isotropic and regardless of their orientation they appear to have no effect upon the light which enters them, other than single refraction and the absorption giving rise to their transmitted light color. Examples of isotropic substances are those which crystallize in the cubic system (including most metals), and those which can be classified as amorphous (glasses).

Anisotropic substances exhibit more than one index of refraction, that is, anisotropic materials possess the property of resolving the vibrations of light which enters them into component vibrations which are plane polarized, but vibrate in different planes and travel at different rates through the crystal. The difference between the indices of the rays gives the strength of birefringence and is characterized as strong or weak. The identification of anisotropy in inclusions of weak birefringence, that are transparent or translucent, is especially difficult owing to the disturbing effects of internal reflection. Thus, materials of weak birefringence appear to behave the same as isotropic ones under reflected plane polarized light with nicols crossed. Opaque isotropic inclusions will remain dark in all positions when the specimen is rotated in the plane of its polished surface, the reason for this being that the plane polarized light suffers no change in its state of polarization when reflected vertically from any plane surface of the isotropic substance. Thus the direction of vibration is unchanged and if the nicols are crossed the reflected light will be extinguished by the analyser.

Anisotropic substances when examined with completely linearly polarized reflected light, disturb the condition of the plane polarized light beam reflected vertically by their surface. These disturbances may show themselves in two ways. Most important of these changes is the resolution into components of the plane of vibration. Due to this resolution into components, the reflected light will have a component in the vibration direction of the analyser and some light will pass through it. Rotation of properly oriented crystals of the anisotropic substance will cause the reflected light to vary from extinction to maximum brightness four times in 360° rotation of the stage, in contrast to opaque isotropic substances which remain dark between crossed nicols as during a 360° rotation. Only in the positions in which the principal directions of vibration (axes of optical elasticity) of the anisotropic surface coincide with the vibration directions of the nicols will there be extinction. At these positions there is no resolution into components of the plane of vibration of the reflected light.

The incoming linear polarized light can also be reflected as circular or elliptical polarized light, two special cases of the resolution into components, which is produced because of the birefringence of the material. These are the principal disturbances which cause a change in the nature of the polarized light if brightness of the beam has been restored. These two effects can be distinguished from one another by means of compensators which can be added between the polarizer and analyser. The function of the compensator is to introduce any desired phase difference into polarized light. A quartz wedge is an example. Thus by means of compensators, polarized light with any amount of ellipticity may be changed to plane polarized light which is the only type of polarized light capable of being entirely absorbed by the analyser nicol.

These disturbances of the plane of vibration can vary in regard to the degree to which they can be evidenced so that we observe a strong or a weak birefringence.

The magnitude of these effects in most cases are rather small, particularly with inclusions exhibiting weak birefringence, so that it is of great importance that the incoming polarized light be wholly plane polarized as otherwise any small elliptical polarization effect from the inclusion may be missed, and the absence of observable anisotropic behavior under crossed nicols will not indicate that the inclusion may be actually isotropic. The effects obtained by internal reflection and anisotropic behavior are superimposed in translucent anisotropic inclusion minerals. A thorough knowledge of the optical system being used, of the behavior of polarized light and also of the optical properties of inclusion minerals is required to interpret microscopic observations.

Identification Tests for Inclusions—The following scheme of identification contains tables of properties of substances which may be encountered as nonmetallic inclusions in the examination of steels and irons. It should be noted that inclusions in metals rarely consist of a single pure component and their properties are there-

fore unlikely to coincide precisely with those of the minerals to which they are related. Further, the methods just described for the examination of polished metallographic specimens are sometimes incapable of distinguishing some of their optical properties. For more detailed information on the minerals given in the tables, and for information on other possible "inclusion minerals," the investigator is referred to E. S. Dana "Textbook of Mineralogy" edited by W. E. Ford, A. N. Winchell "Microscopic Characters of Artificial Minerals," and H. Schneiderhöhn and P. Ramdohr "Lehrbuch der Erzmikroskopie," v. 2.

The minerals described however, will help to identify inclusions on the basis of optical character. Certain inclusions derived from refractories occur as minerals and the use of these tables will help to identify such inclusions which might be identified as other substances if the scheme for etching identification tests were used alone.

The tables also include the characteristics, which may be observed by reflected plane polarized light with crossed nicols, of inclusions in steels and irons similar to the composition of the minerals.

The properties of the minerals described in the tables (a) to (f) inclusive are for minerals of the particular allotropic modification as stated and do not correspond in all cases to the properties of inclusions that may occur in steels and irons of quite similar chemical composition.

For the convenience of the investigator an etching scheme is also included to enable the identification of certain opaque oxides frequently encountered as well as other isotropic substances which can sometimes be identified by their color and shape and can be further distinguished by their etching characteristics.

The investigator should make all of his observations by reflected plane polarized light with crossed nicols, first, before applying the etching tests to his sample for identification purposes.

Proper use of the scheme should employ the following procedure:

1. Examination of the inclusions "as polished" with ordinary reflected white light at X200, X500 or X1000; to observe the size, shape, reflected light color, and distribution of the inclusions.

2. Selection of several representative fields for further investigation by reflected plane polarized light with crossed nicols for observation of isotropic or anisotropic behavior, opaqueness or translucency, and transmitted light color.

3. Complete identification of opaque inclusions and others when in doubt with appropriate etching tests.

A more complete report of this article will appear in Trans. A.S.M.

Distinctions to Be Observed for the Identification of Inclusions in Steels and Irons With Reflected Polarized Light

System Used Below for Property Designation

- | | |
|-----------------------------------|--|
| 1. Name and Formula | |
| a. Crystal system | e. Color by transmitted white light (plane polarized light crossed nicols) |
| b. Melting point | f. Index of refraction |
| c. Hardness (Mohs' Scale) | g. Common occurrence |
| d. Color by reflected white light | h. Remarks |

Inclusion Minerals Which Always Remain Dark During 360° Rotation

- | | |
|--|--|
| 1. Ferrous oxide, FeO | |
| a. Isometric | g. In scale, and as more or less rounded single phase globules in rimming and similar steels low in silicon and manganese. |
| b. 1360°C., 2480°F. | h. Somewhat malleable at S R T (steel rolling temperatures). |
| c. 5.5-6.5 | |
| d. Medium grey | |
| e. Opaque | |
| 2. Magnetite, FeO.Fe ₂ O ₃ | |
| a. Isometric | e. Opaque |
| b. 1327-80°C., 2421-2516°F. | g. In scale |
| c. 5.5-6.5 | h. Not malleable at S R T |
| d. Light grey | |

3 Titanium nitride, TiN

- a. Isometric
- c. 9-10
- d. Yellow
- e. Opaque
- g. In steels and irons treated with ferro-titanium.
- h. Not malleable at S R T. May contain TiC in solid solution. Color in reflected white light varies from yellow to pink to violet with increasing carbon content. Pink sometimes called cyano-nitride. The inclusions are strongly angular and easily pitted in polishing.

4. Zirconium nitride, ZrN

- a. Isometric
- b. 2950°C., 5342°F.
- d. Yellow
- e. Opaque
- g. In steels and irons treated with ferro-zirconium.
- h. Not malleable at S R T. May contain ZrC in solid solution which produces varying colors by reflected white light: Orange, brown, violet, blue. The inclusions are strongly angular and they may be distinguished from TiN by etching tests. They are softer and easier to polish than TiN.

5. Vanadium nitride, VN

- a. Isometric
- b. 2000°C., 3632°F.
- c. 9-10
- d. Pink
- e. Opaque
- g. In vanadium steels. These inclusions resemble titanium cyano-nitride.

*Translucent Isotropic Inclusion Minerals***1. Manganous oxide, manganosite, MnO**

- a. Isometric
- b. 1700°C., 3092°F.
- c. 5-6
- d. Very dark grey
- e. Green
- f. $N = 2.16$ (Li)
- g. In steels and irons high in manganese which have not been deoxidized with other more effective deoxidizers, for example, aluminum and silicon.
- h. Somewhat malleable at S R T. Usually contains more or less FeO in solid solution. Color by reflected white light changes from dark grey to medium grey with increase in FeO. Color by transmitted light changes from green to red or brownish red to opaque with increase in FeO.

2. Manganous sulphide, alabandite, MnS

- a. Isometric
- b. 1620°C., 2948°F.
- c. 3.5-4
- d. Medium grey
- e. Green
- f. $N = 2.70$ (Li)
- g. Steels and irons except those with very low manganese content.
- h. Very slightly malleable at S R T, malleability increases with increase in FeO in solid solution. Usually contains FeS in solid solution. In stainless steels probably also contains Cr in solid solution. Color by reflected white light changes from medium grey to greyish white, with pearly luster, with increase in FeS. Color by transmitted white light changes from green to greenish yellow or brown to opaque with increase in FeS.

3. Iron aluminate, hercynite, $\text{FeO} \cdot \text{Al}_2\text{O}_3$

- a. Isometric
- b. Above 1700°C., 3092°F.
- c. 7.5-8
- d. Medium to dark grey
- e. Colorless, green, yellow brown, reddish brown, opaque when rich in iron oxides.
- f. $N = 1.80$
- g. In steels and irons treated with aluminum and in some inclusions derived from refractories.
- h. Not malleable at S R T. Change in color and translucence due to solid solution. Opaque varieties are lighter grey by reflected white light. Frequently occurs as equiaxed euhedral crystals. Not as difficult to polish as inclusions rich in Al_2O_3 .

4. Chromite, $\text{FeO} \cdot \text{Cr}_2\text{O}_3$

- a. Isometric
- b. 5.5
- d. Medium grey
- e. Red, reddish brown, yellowish brown, or opaque depending on the thickness.
- f. $N = 2.07-2.16$
- g. In steels and irons which contain chromium.
- h. Not malleable at S R T. Frequently occurs as equiaxed euhedral crystals, and also observed to be of eutectic nature. These inclusions are easily polished.

5. Silica glasses

- a. Noncrystalline
- b. Variable
- c. Approximately 7
- d. Light to very dark grey, sometimes with bright internal reflections.
- e. Colorless or all colors depending on contamination with other oxides.
- f. Variable
- g. In steels and irons which contain silicon which have not been thoroughly deoxidized with other more effective deoxidizers, for example, aluminum; and in some inclusions derived from refractories.
- h. Varying degrees of malleability at S R T. May be more or less milky because of precipitation of other minerals in finely divided state within the glass on cooling. In cast or weld metals transparent spherical glassy silicates exhibit the dark optical cross by transmitted white light.

Opaque Minerals Showing Anisotropic Behavior

1. Ferrous sulphide, troilite, FeS

- a. Hexagonal
- b. 1180-1190°C., 2156-74°F.
- c. 3-4
- d. Light tan or yellow
- e. Opaque
- g. In steels and irons very low in manganese
- h. Malleable at S R T. Under reflected plane polarized light with nicols crossed, properly oriented grains show four extinctions in 360°.

*Translucent Anisotropic Minerals with Weak Birefringence*1. Alumina, corundum, Al_2O_3

- a. Hexagonal
- b. 2050°C., 3722°F.
- c. 9
- d. Medium grey
- e. Colorless
- f. $N = 1.77$ Ne = 1.76 (Na)
- g. In steels and irons treated with aluminum, and in some inclusions derived from refractories.
- h. Not malleable at S R T. Color by transmitted light changed variously by impurities in solid solution. Occurs as equiaxed or elongated grains with irregular surfaces, or euhedral crystals.

These have a tendency to group together in clumps or small clouds of particles. During rolling or forging these groups are formed into irregular rows of particles in the direction of working. These inclusions are rarely pure and may contain FeO and SiO_2 . The inclusions rich in Al_2O_3 are difficult to polish and frequently their anisotropic behavior is masked by reason of their transparency and highly reflecting metal inclusion interface, or by rounding the edge of the cavities left by their removal.

2. Mullite, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$

- a. Orthorhombic
- b. 1816°C., 3301°F.
- c. 7.5
- d. Medium to dark grey

- e. Colorless, pink
- f. $N_g = 1.654$, $N_m = 1.644$, $N_p = 1.642$
- h. Frequently occurs as long euhedral crystals in glass inclusions.

3. Quartz, SiO_2

- a. Hexagonal
- b. 1600-1750°C., 2912-3182°F.
- c. 7

- d. Medium to dark grey
- e. Colorless
- f. $N = 1.55$, $N_o = 1.54$

4. Cristobalite, SiO_2

- a. Pseudo-isometric (tetragonal?)
- b. 1696°C., 3085°F.
- c. 6-7
- d. Medium to dark grey

- e. Colorless
- f. $N_o = 1.487$, $N_e = 1.484$
- h. Usually associated with glass.

*Translucent Anisotropic Minerals with Strong Birefringence*1. Fayalite, $2\text{FeO} \cdot \text{SiO}_2$

- a. Orthorhombic
- b. 1205°C., 2201°F.
- c. 6.5
- d. Medium to dark grey

- e. Colorless, light green, yellowish green, yellowish brown.
- f. $N_g = 1.886$, $N_m = 1.887$, $N_p = 1.835$
- h. Frequently contains $2\text{MnO} \cdot \text{SiO}_2$ in solid solution.

2. Ferric oxide, hematite, Fe_2O_3

- a. Hexagonal
- c. 5
- d. Medium to light grey

- f. $N_o = 3.22$, $N_e = 2.94$ (Na)
- g. Frequently occurs as outer layer of scale.

3. Chromic oxide, Cr_2O_3

- a. Hexagonal
- b. 1900°C., 3452°F.
- d. Medium to light grey
- e. Green, depending on the thickness

- f. $N = 2.5 \pm$
- g. In stainless steels and other high chromium materials
- h. Not malleable at S R T. These inclusions are harder than chromite.

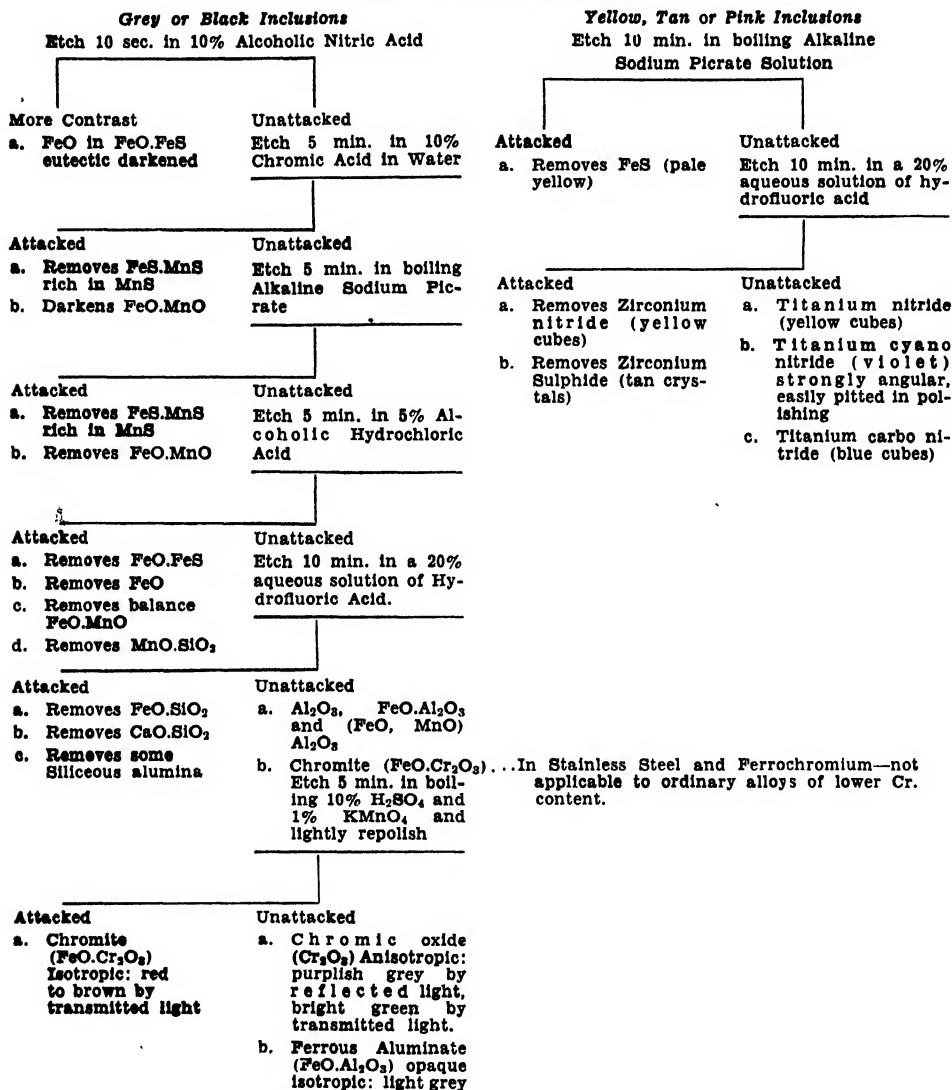

4. Aluminum Nitride, AlN

- a. Hexagonal
 - b. 2150-2200°C., 3902-393°F.
 - d. Dark to very dark grey
 - f. Birefringence (not available).
- Often show brilliant polarization colors.

- g. In chromium produced by the aluminic thermic process and in chromium steels containing aluminum.
- h. Frequently occurs as euhedral crystals.

McQuaid-Ehn Test

By H. W. McQuaid*

Purpose of Test—The McQuaid-Ehn Test was developed in 1922 as a result of an extensive investigation into the effect of melting furnace practice on the hardenability of plain carbon case hardening steels. It was found that by carburizing at 1700°F. in a solid carburizer which would develop a definite hypereutectoid zone, and then permitting the material to cool slowly enough to develop a pearlitic struc-

Fig. 1—Case structure of normal steel after McQuaid-Ehn test. White cementite network around dark pearlitic grains. $\times 100$.

Fig. 2—Same as Fig. 1 at $\times 1000$.

ture with free cementite in the hypereutectoid zone, there would be a definite structure developed depending upon the practice used in the melting furnace. By this means it became possible to predict from the carburized test the reaction of the final carburized product in quenching.

Since this test was first introduced it has been extended to cover not only plain

*Metallurgist, The Republic Steel Corp., Cleveland, Ohio.

This article was not revised for this edition.

carbon carburizing steels, but also alloy steels in all the commercial grades and the plain carbon steels including the tool steel ranges.

The importance of having methods of connecting properties inherent in a given heat of steel with the results to be expected in heat treatment and in the finished product, has resulted in many investigations into the characteristics developed by the McQuaid-Ehn Test. Other methods for the same purpose are given on page 754.

Pearlitic Structure Required—In order to properly make the McQuaid-Ehn Test, it is necessary to develop a pearlitic structure within the grain of the hyper-

Fig. 3—Case structure of abnormal steel after McQuaid-Ehn test. White cementite network with free ferrite (white) around dark lamellar pearlitic grains. $\times 100$.

Fig. 4—Same as Fig. 3 at $\times 1000$.

eutectoid zone after case carburizing. This requires the use of a carburizing compound which will develop a sufficient excess of cementite to permit, after the formation of the pearlitic structure within the grain, a clear indication of the disposition of the cementite itself. The work to be tested should, therefore, be carburized in a solid carburizer containing sufficient energizer to give a carbon content in the case well above the eutectoid range. There are many commercial carburizing compounds on the market which can be used for this purpose and as a

rule the standard carburizing compound used in the average plant will be found satisfactory.

Carburizing Temperature and Time—The work should be carburized at a temperature which is as close to 1700°F. as is commercially possible. However, very little difference will be found with a variation in temperature of from 1675-1725°F.

The time at temperature is determined by the depth of case obtained, and for most purposes it is only necessary to hold at temperature long enough to develop a sufficient hypereutectoid zone to be readily studied at 100× magnification. It is

Fig. 5—Case structure of coarse grains after McQuaid-Ehn test. $\times 100$.

Fig. 6—Case structure of fine grains after McQuaid-Ehn test. Same composition as Fig. 5. $\times 100$.

better for most purposes to carburize until a case of approximately 0.050 in. is obtained, which will provide ample hypereutectoid zone for satisfactory study.

Cooling from Carburizing Temperature—The cooling time is governed to a large extent by the alloy content. In order to develop a satisfactory *pearlitic* structure in the hypereutectoid zone, the cooling rate must be very slow in the case of high alloy air hardening steels and can be relatively fast with the low carbon, low manganese steels containing no alloy. The cooling rate can be determined only by experience and depends not only on the alloy content but also on such factors as the size of carburizing container, size of specimen, and heating furnace. With plain carbon steels, the carburizing can be done in a commercial furnace and air cooled in the standard carburizing container. With the air hardening steels, such as the high nickel and chromium-nickel-molybdenum series, it is necessary to cool in the furnace. Where the carburizing is done in a laboratory furnace, it is quite common

to cool all tests in the furnace and with high alloy steels it has been found necessary to cool in the furnace at a very definite maximum rate.

The following minimum cooling rates through the critical range may be found satisfactory: 4 hr. for S.A.E. 2315 and 4615; 8 hr. for S.A.E. 2512; 16 hr. for Krupp steel (Ni 4%, Cr 1.5%); and 3 hr. for the other steels such as the plain carbon. 3115 and 6115.

Interpretation of Results—The interpretation of the test depends upon the examination of the pearlite and cementite in the hypereutectoid zone. In a strictly normal steel the structure within the grain boundaries is completely pearlitic, and if the grain is coarse the cementite exists as well defined lines of fine but continuous formation at the crystal boundary, as shown in Figs. 1 and 2. In a strictly abnormal steel the pearlite, if it is present at all as such, will be found to be very coarsely and irregularly lamellar and to have broken down completely at the grain boundaries to form massive cementite and free ferrite (Figs. 3 and 4). Here the cementite will be distinguished as ridges having a white background of ferrite. Between these two extremes will be found many types in which the pearlite becomes more coarsely lamellar as the steels become more abnormal, and there is an increasing amount of free ferrite surrounding the cementite at the grain boundaries. It will also be noted that there is a tendency for the cementite to become thicker and in some cases to become a discontinuous series of elongated particles.

Consideration of Grain Size—It was noticed at the time that this test was first developed that there was a variation in the size of the grain in the hypereutectoid zone from one heat to another and that this variation in grain size also served as an indication of the characteristics of the finished heat treated piece not only as far as hardenability is concerned but also in regard to the distortion and physical properties as well.

As usually made, particularly in the plain carbon steel, coarse grained steel will be quite normal with an increasing tendency toward abnormality as the grain size decreases. The coarse grained normal steels respond better to quenching, harden more deeply, and tend to distort considerably more than the finer grained more abnormal steels. The coarse grained normal steels have usually much lower resistance to impact and for this reason the finer grained steels are preferred for applications where resistance to shock loading is necessary. Because of the fact that the fine grained steels exhibit a much reduced tendency toward grain growth, they are usually preferred especially in the alloy grades for quenching directly from the carburizing temperature. In the plain carbon grades the difficulty met with in hardening because of soft spots is greatly increased with the fine grained, more abnormal steels, so that it is often necessary to quench these steels in a caustic or similar solution after carburizing.

The coarser grained steels respond more readily to the usual normalizing temperature to form a coarsely lamellar pearlite and hence are preferred in some plants because of the improved finish obtained in machining. By using a higher normalizing temperature, approximately 1800°F., to overcome the inherent resistance to grain growth in the finer grained steels, it is possible to improve the machinability of the fine grained steels to equal that of the coarse grained steels.

There is at present some difference in opinion as to the relative effects of normality and grain size. It is quite evident that the normality and the grain size are two independent characteristics and that steel can be made if desired which is fine grained normal or coarse grained abnormal. This is entirely a matter of furnace practice, but under present conditions most of the fine grained steels are slightly abnormal and the coarse grained steels are normal, and the desired characteristics can be commercially obtained by proper selection according to grain size. For this purpose there are available grain size charts which permit of classification according to grain size as revealed by the McQuaid-Ehn Test.

Austenitic Grain Size in Steel

By E. C. Bain* and J. R. Vilella†

PART I. SIGNIFICANCE OF GRAIN SIZE

Introduction—Probably no subject relating to the heat treatment of steel has received more attention in the last few years than that of austenitic grain size. This interest came about as a response to the need for a rational understanding of those more subtle, but important, factors of steel quality which cannot be explained by the composition of the steel as ordinarily reported in the usual analysis. In brief, the explanation was found to lie largely in the grain size of the austenite, established during the final heating above the critical range. The *extra analytical* properties finally secured depend in large part upon the actual grain size of the austenite which transforms to set up the microscopic structure existing in the heat treated steels as tested and used. Once the trends of austenitic grain growth in steel were understood it was apparent that a clear cut, positive correlation existed between properties or behavior and the true mean grain size established in the final heating. This close relationship seemingly does not exist between the securable properties and any *quasi* grain size which might have been established at some other temperature, or with some treatment, not used in the practical final heat treatment which is responsible for the properties. This reasonable circumstance was seemingly overlooked for a time, owing perhaps to a lack of confidence in means of quickly ascertaining the austenite grain size of any specimen of steel about to be quenched in any suitable manner. Yet this is the grain size which would be expected to have a direct, rather than fortuitous, significance. Throughout this article *grain size* will always mean the true austenitic grain size established at elevated temperature in an indicated significant heating.

The pioneer contributions to this advance in the technology of heat treated steels, both in manufacture and in use, came from several sources. In Sweden the study¹ progressed as an inquiry into the characteristic attributes, particularly of acid open hearth tool steel. Another approach² was that which related to the hardenability of comparatively low alloy, low carbon, carburizing steels quenched directly from the carburizing box. A more advanced development³ of this subject, on the part of manufacturer and user, was that of fine carbon tool steels of controlled hardenability (and toughness) accomplished without significant changes in analysis, and the subsequent extension of these achievements into the steels of greater tonnage. All these studies converge in the building up of a simple concept of grain size effects and it is toward the setting forth of this simplification as applied to medium and high carbon and low alloy heat treated steels, that this article is directed.

The Usefulness of the Older Observations—It was not unknown in old art that a coarse fracture of a hardened and broken piece of steel accompanies excessive brittleness, and that equally hardened steel which requires greater effort in breaking exhibits a finer, "silky" fracture. The many individual facets of the broken surface are large in the first case and small in the second. To what the size of the individual facets refers, and upon just what this corresponding coarseness or fineness depends, was, however, not obvious, and has only more recently been known. Another observation was probably made long ago; similar steels, in sections too large to be hardened throughout, hardened more deeply, in a certain medium, whenever the fracture appearance was coarse, and less deeply when the fracture was fine. Some twenty years ago, more or less, certain manufacturers were introducing an alloying element to preserve the fine fracture and its attendant toughness, and adding extra manganese to restore the deeper hardening characteristics. When a single bar or heat of steel was under consideration it was observed long ago that high heating temperatures, as in the Metcalf test, induced the deeper hardening and the attendant coarser fracture but any cause and effect relationship between coarseness and depth of hardness penetration in the quenched piece was not specifically mentioned until more recently. Indeed it was erroneously supposed by some that the quenching rate in any medium was universally accelerated if the steel was quenched from a higher temperature. This is now known

to be untrue⁴ in any general sense. Since steels of almost identical composition (insofar as the ordinary elements reported in an analysis are concerned) are available, each of which will develop its own particular grain size at a certain temperature, grain size variation may be studied quite independently of the heating temperature, which may thus be the same for all. When the interest centers in the same identical steel then heating temperature or heating schedule is varied to produce the grain size contrast. By employing both methods of grain size control the broad effects have become familiar.⁵ In a general way the effects of the previously existing austenite grain size may be summed up in Table I.

Table I
Effects of Previously Existing Austenite Grain Size

Property	Trends in Heat Treated Steel Products	
	From Coarse Grained Austenite (No. 5 and Above)	From Fine Grained Austenite (Finer than No. 5, 5-8)
Hardenability	Deeper hardening.....	Shallower hardening.....
Toughness at same hardness.....	Less tough.....	Tougher.....
Distortion	More distortion.....	Less distortion.....
Quenching cracks.....	More prevalent.....	Usually absent.....
Grinding cracks.....	More susceptible.....	Less susceptible.....
Internal stress.....	Higher.....	Lower.....
Retained austenite.....	More.....	Less.....
<i>For Annealed and Normalized Products</i>		
Machinability	(Rough) better.....	(Rough) inferior.....
Machinability (special cases).....	(Fine finish) inferior.....	(Fine finish) better.....
Formability (special cases).....	Superior.....	Inferior.....

Before considering the yard stick for grain size evaluation and the technique by which it is easily accomplished, it is desirable to consider the habits of austenite as it forms upon heating and establishes the grains which later grow in characteristic ways (and become of such importance).

The Formation and Growth of Austenite Grains—When a piece of carbon or low alloy steel is heated above the so-called critical point the ferrite and carbide react with one another to form austenite. The austenite is a crystalline phase differing distinctly from either the carbide or ferrite of which the steels under consideration are inevitably composed. Like any metal composed of a solid solution, it exists in the form of polyhedral grains. This reaction begins at a number of points, of necessity, in the interface of the carbide (particles or plates) and the ferrite. In each such growing particle of newly formed austenite, carbon and iron and other elements from the carbide particles are dissolved as well as iron and other elements also from the ferrite. Each little island of austenite grows until finally it reaches to its similarly growing neighbors.⁶ In the ideally simplified case there would be just as many grains of austenite as there were separate original nuclei, and in a fairly coarsely spheroidized steel this is nearly realized. In the general case, some of the islands of austenite must, of course, grow more vigorously than others and, therefore, when a large grain encounters a small one the small one is forced to shift its orientation layer by layer, and thereby, as it loses its identity, it is absorbed into the larger grain. Probably this happens frequently in certain steels and rarely in others. Now if the steel is far from eutectoid in composition and is heated below the A_{c1} or A_{cm} temperature, some islands of ferrite or cementite will remain unabsorbed regardless of period of heating. These undissolved proeutectoid constituents appear to block grain growth so that this initial set of austenite grains are preserved even after long heating. When the temperature of heating is above A_{c1} or A_{cm} , any ferrite usually disappears quickly enough, but the carbide, although ultimately soluble, dissolves rather slowly so that, depending upon its coarseness, more or less of the carbide persists even after surprisingly long time intervals. It is important here to note that the first grain size of the austenite depends largely upon the number of nuclei and that so long as any moderate amount of carbide remains these grains do not greatly change.

In pearlitic steels the effective nuclei are often located in the interior of a region of lamellae, while in spheroidized steel each spheroid of carbide is a poten-

tial nucleus. When the spheroidization is fine many such nuclei are ineffective because of the mechanism mentioned above. However, at ordinary quenching temperatures the original austenite grain size pattern is largely retained and this is termed the "uncoarsened grain size" to which almost all practical heat treating of carbon steel relates. The number of nuclei seemingly depends upon:

1. Previous mechanical and heat treatment, as it affects:
 - a. Distribution of carbide, lamellar or spheroidal, i. e., the structure.
 - b. Fineness of carbide dispersion.
 - c. Homogeneity of steel.
 - d. State of stress or deformation.
2. Composition of ferrite and carbide.
3. Nonmetallic inclusions:
 - a. Submicroscopic.
 - b. Microscopic.

Subsequent changes in the grain size of the austenite occur with heating as it reaches toward and beyond the normalizing range of temperature. Many steels not so made as to restrict grain growth begin to undergo mild coarsening about as soon as the major part of the carbide (or ferrite) is dissolved. With rising temperature, such steels appear to coarsen rather regularly without any abrupt changes, presumably by the successive coalescence, here and there, of two or sometimes three grains to form one new grain. At any rate there is at no point any marked disparity of grain size. When a special, less soluble, carbide exists, as for example in vanadium steels, the carbide particles persist to astonishingly high temperatures such as 1750-1800°F., and little grain growth occurs so long as many such vanadium-rich carbide particles remain.

In similar manner certain nonmetallic substances appear to accomplish this same inhibition to grain growth. This broad effect of inert particles has long been known in the manufacture of tungsten filament wire, in which case the extremely inert and refractory oxide of thorium present as visible particles, at least in part, acts as the grain growth inhibitor.

An interesting effect of these so-called grain growth inhibitors is that when they finally become ineffective at some elevated temperature, either as a result of solution or coalescence, or by mere inefficacy or insufficiency, the degree of grain growth is likely to be greater than in a steel free from such restraint. Such steels retain a fine grain almost unchanged during heating at successively higher temperatures until abruptly, here and there, a single large grain forms out of as many as 100 or more former small grains. Prolonged heating, or a rise in temperature, will generally convert the remaining fine grains to the same type of large grain as first formed upon reaching the coarsening temperature. Inhomogeneities of the steel tend to broaden the temperature range of two distinct grain sizes. This state of affairs in the marked grain growth range is sometimes spoken of as "duplexing". It has no special significance, merely marking a natural transition stage from fine to coarse grains, when the change is large and fairly abrupt and unfinished.

It should be borne in mind that the persistence of carbide and attendant retention of small grains is often a matter not of equilibrium but of rate of solution and carbide frequently remains undissolved for 30 min. or more in eutectoid or even hypoeutectoid steel heated well into the pure austenite (equilibrium) temperature range.

PART II. DETERMINATION OF AUSTENITIC GRAIN SIZE

Introduction—In Part I, the grain size established in austenite at various temperatures has been discussed in a qualitative or comparative way. It now becomes necessary to go into greater detail and to choose some quantitative basis of grain size estimation. Now, grains are solid bodies, and to be meticulously correct one should speak of an average grain size in terms of volume, such as fractions of a cubic inch or a cubic millimeter; or one could better use the reciprocal, so many grains per cubic inch or cubic millimeter. Actually, this is unnecessary and probably confusing. Grain size estimation or grain counting is finally accomplished by viewing a polished *plane* section under the microscope and the boundaries of the grains as viewed lay out a network on a *plane* surface. Now the number of grains per unit area so sectioned upon a plane, or the average area of these

Fig. 6

rough polygons serves quite as well as a measure of grain size as would a figure based on three dimensions or volume. If one cares to do so he can always think of the grains as solid bodies while reporting in terms of their mean sections on a representative plane. The actual units employed in such grain size estimates are not uniform for different metals in different countries. The common terms for reporting grain size are:

1. Grains per sq.mm.
2. Average area of grain in sq.mm.
3. Mean diameter of grain (in mm.).
4. Arbitrary numbers (exponential), Timken, A.S.T.M., index based upon the formula.

$$\text{Number of grains per sq.in. at } 100X = 2^{N-1}, \text{ in which the grain size index} = N.$$

The designation mean diameter (3) is fortunately not much used since it is not easily estimated directly and as a derived number is ambiguous and less useful than the direct observation. Any scheme showing number of grains per unit area (either of specimen or microscopic image at known magnification) is vastly preferable.

Practically all austenitic grain size studies and specifications in America refer to the Timken, A.S.T.M. index numbers. For convenience they are tabulated with corresponding dimensions in Table II, and extended somewhat beyond the usual range employed. In Table II, the last column headed "Grain Boundary Area, mm.² per mm.²," shows the minimum possible interface area. The effective intergranular surface will be greater, particularly in the finer grain sizes, due to the undissolved carbide particle surfaces and to irregularities in the true austenite grain boundaries.

It is often desirable to match the microscopic image discussed below with the standard network charts, such as are included herewith (Fig. 1-8), using a magnification either lower or higher than 100X, respectively, for coarse or fine grains. The following rules apply:

- For 50X, report 2 numbers lower than matching chart.
 For 200X, report 2 numbers higher than matching chart.
 For 400X, report 4 numbers higher than matching chart.
 For 800X, report 6 numbers higher than matching chart.

Idealized grain boundaries in a hypothetical hexagonal network are shown in Fig. 1-8 for the corresponding A.S.T.M. grain sizes as tabulated in Table II. These are probably the best comparison standards for general grain size estimation.

Table II
Comparison of Systems for Reporting Grain Size

Timken, A.S.T.M. No.	Grains per sq.in. of Image at 100X			Grains per mm. ²	Mean Area per grain, mm. ²	Grains per mm. ² Approx.	Grain Boundary Area, mm. ² per mm. ²

Some of the data of this table are from unpublished work of R. H. Aborn and J. J. B. Rutherford.

Preparation and Microscopic Examination of Specimens for Grain Size Rating—Thus far it has been assumed that the grains could be rendered clearly visible in a microscopic specimen and an estimate of their size arrived at either by counting over a known area of image at known magnification, or by comparing such images

on the microscope ground glass with charts having standard graded grain size patterns marked out. This is, in general, easily done, especially for grain sizes No. 6 or coarser. Occasionally it is more time consuming for finer grain sizes but never impossible. In principle, the problem of grain size determination in austenite is rendered more complex than that in brass, for example, because one must estimate the grain size of a constituent which is no longer present. If one had a means of examining under a microscope the heated steel ready to be quenched this complication would not arise, but such technique is not practical. Fortunately, how-

Fig. 9—Ferrite network properly developed for grain size estimation in hypoeutectoid steel, X300. Fig. 10—Carbide network properly developed for grain size estimation in hypereutectoid steel, X300. Fig. 11—Black etching network of fine pearlite properly developed for grain size estimation in incompletely hardened eutectoid steel, X125. Fig. 13—Grain size developed in fully hardened and tempered steel (troostite or sorbite) for grain size estimation, X100.

ever, austenite transforms in such a way as to reveal its former grain boundaries unequivocally. This comes about through three circumstances:

1. Proeutectoid rejections in either hyper- or hypoeutectoid steels can generally be forced to the grain boundaries to form a complete, or nearly complete, network.
2. Transformation reactions even in eutectoid steel begin dominantly in the grain boundaries and may be interrupted when a network is developed.
3. Martensite has limits of orientation depending upon that of the parent austenite grain and hence can, with suitable agents, be etched much like a pure metal to develop contrast among grains.

In some respects the fact that the grain size of austenite is estimated upon its decomposition products and not upon the constituent itself is an advantage; for this circumstance permits outlining the grain boundaries with constituents which may have great visual contrast with the main portion of the grains. Even under the worst conditions the problem, however unique, is not more difficult than that for brass or other single constituent metals. As it happens, carbon or low alloy steels with a carbon content somewhat remote from the eutectoid, that is, distinctly hypoeutectoid or hypereutectoid, reject, upon slowly cooling through the transformation range, either ferrite or carbide, respectively; the rejection of these proeutectoid constituents occurs largely at the grain boundaries after which the remainder of the austenite transforms to a black etching pearlite. The transformation of eutectoid austenite, beginning characteristically in the grain boundaries, makes possible the formation of some fine pearlite (nodular troostite) in the grain boundaries after which the remainder of the austenite may be caused to transform to light etching martensite. Thus eutectoid steels, from which no separate boundary constituent may be rejected, may quite as easily have the grain boundaries clearly laid out. It is obviously of no consequence which is darker, the boundary or the interior body of the grain.

Now, any steel sample heated at any temperature, depending upon carbon content, above A_{c1} , A_{c2} , or A_{cm} is made up of austenite (in which carbide may be present or not), which is composed of grains and an interest may exist in the size of those grains; the foregoing paragraph shows how it is always possible to learn what this grain size may be. Often the steel may be normalized in handling and it will be the high temperature austenitic grain size in which interest centers. In that case one may either simulate the normalizing treatment in a small laboratory furnace and establish the grain size in question, or a piece may be carried along in the commercial furnace. In any event the grain size will have been established at the conclusion of the heating period and the only problem thereafter lies in so cooling the specimen as to make that grain size clearly readable under the microscope. More often the interest lies in the grain size in the steel as heated for the final quench (water, oil, or air) and in this case also either the laboratory furnace may be employed or a piece going through commercial treatment may be selected for grain size examination. In any case it is only the austenitic grain size actually established in the particular heat treatment under consideration which can infallibly correlate with the steel properties to be secured. The austenite grain size is not affected in any way by the kind of cooling applied and any representative specimen selected for examination from the heating furnace may be cooled wholly as desired on the basis solely of making its grain size apparent.

For example, if it should be desired to secure a steel which would not coarsen to an extent beyond a No. 5 grain size, and the customary heat treatment is nominally at 1475-1500°F., then one should cut a specimen of dimensions suited to the application and so heat it, either along with a commercial batch, or in a small furnace for the same period and then cool it, as indicated below, to give the best marking out of grain size. If the steel is normalized or homogenized prior to such heating for hardening then this treatment should preferably precede the heating for test. To take care of possible furnace irregularities some prefer to heat 50°F. or even 100°F. higher than the commercial schedule, on the assumption that if a steel does not coarsen at 1550°F. it certainly will not do so at 1475°F., which is generally true. Testing at much higher temperatures than employed in practice is not correct in grain size study because the test then departs too much from the conditions in which interest centers and valuable information is lost.

Another example might be cited in which a certain degree of coarsening is desired in the normalizing range. In this case the proper preferred normalizing

temperature should be used either in the commercial furnace or in a laboratory furnace for the customary period of time.

The essential point is, that for pertinent information as related to quenching and tempering and the final properties of heat treated steel the grain size should be established at the approximate quenching temperature. For useful information on grain size effects in other heating, such as normalizing (or forging), the higher temperatures employed therein should be used in the grain size determination also. It will be seen that failure to observe this consistent procedure may result in erroneous conclusions.

Having developed the grain size in the properly heated, and therefore austenitic, steel, the cooling is carried out in such a way as best to reveal this grain size. This will vary with the type and carbon content.

Hypoeutectoid Carbon Steels—In most cases with a carbon content between 0.25 and 0.60%, it will be sufficient merely to cool a specimen about $\frac{1}{2}$ in. in dia. in air. The ferrite will form chiefly in the grain boundaries and mark out the grains as in Fig. 9. When the grain size is small, complete envelopes (particularly of ferrite) will generally not form, but this offers no difficulty. One austenite grain still forms, in general, only one area of dark pearlite so that the eye readily recognizes the grains either for counting or for comparison.

When the composition is only slightly hypoeutectoid the steel may either be treated in accord with directions below for eutectoid steel, or may be cooled to about 1340°F. and held there 10 or 15 min. before final cooling. This cooling will generally form a very good network of ferrite.

Hypoeutectoid Alloy Steels—Omitting carburizing steels (discussed below) these steels should in general be cooled by the second method for hypoeutectoid carbon steels, allowing still more time at about 1340°F. Otherwise they may be treated as for eutectoid steels (below). An excellent improvement on this method is to hold at some temperature near 1300°F. for sufficient time to establish a ferrite network and then quench. Subsequent tempering to some 800°F. (a minute is sufficient) develops a black etching sorbite in the body of the grains. The most brilliant contrast develops upon etching. Higher alloy steels require the longer holding time. The optimum can be determined once for all by a series of specimens held for three or four different periods.

Hypereutectoid Steels—These steels are easily cooled to develop a fine carbide network, the best rate depending upon composition. Unless the carbon is above 1.10, they are best treated as eutectoid steels (below). Equally satisfactory results are secured by the method of holding at 1300-1340°F., quenching and reheating roughly at some 800°F. The hypereutectoid zone of a carburized steel is handled in the same way, as discussed below. Fig. 10 shows a carbide network marking out the grains.

Eutectoid Carbon Steel—A specimen of $\frac{1}{2}$ -1 in. dia. is properly heated in the range in question and quenched into water; one end may be kept out of the water. The center, or the unquenched end, will be uniform fine pearlite, in which grain size is not discernible; the outer zones will be martensitic. Between the two will be a zone in which the martensitic body of the grains will etch lightly, while the many nodules of fine pearlite in the grain boundaries will etch black and mark out the grains. When this method becomes somewhat ambiguous in the finest grain sizes, and it is still desired to have an accuracy of one grain size number, the estimation should be made in the fully hardened zone as for hardened steel. Fig. 11 shows grain size marked out by black etching fine pearlite in the boundaries in the transition zone.

Fully Hardened Steel—It may happen that it is desirable to know the grain size established in heating a steel which has however already been quenched, and even perhaps tempered, the latter being the most difficult case. This can also be accomplished by suitable etching of the wholly martensitic structure. Two or more slight repolishings and etches may be necessary. The etching agent (Vilella's Martensite Reagent) which develops contrast between the martensite of individual austenite grains is made up as follows: Dissolve in 95 cc. of ethyl alcohol 1 g. of picric acid and 5 cc. of concentrated hydrochloric acid.

The prior true austenitic grain size may be determined in hardened steel which has been definitely tempered and moderately softened. Indeed, there is an optimum

degree of tempering which provides the greatest contrast among the grains. Fig. 12 shows the structure of hardened steel etched for grain size estimation, and Fig. 13 shows a hardened and tempered steel.

Carburizing Steels—In cases wherein the steel under consideration is to be case carburized and quenched directly from the carburizing box, the important grain size is that established under those precise conditions when the steel is removed from the carburizer; the grain growth characteristics of the steel are often greatly altered by the infusion of carbon, and an examination of the original low carbon steel heated to the carburizing temperature would be misleading (that is, the core of carburized pieces). Accordingly the specimen should be properly cooled so as to develop a carbide network in the high carbon zone when removed at the conclusion of carburization; in brief, handled thereafter exactly as for any hypereutectoid steel. When, however, the carburized steel is to be reheated, the carburized grain is not significant and the specimen should be reheated in accord with practice before cooling to mark out the grains.

Grain size estimation was early carried out upon carburizing steels and the observations upon the hypereutectoid zone were interesting. In the first place, grain size estimation on the microscope is, perhaps, easiest upon hypereutectoid compositions due to the extra contrast of the usually clear carbide envelopes or network. Certain other features* of the carburized structure are, metallographi-

Fig. 14—A comparison of the Jernkontoret and Shepherd fracture standards 1-10, each in terms of the other. Note similarity.

cally, fascinating, and the examination of carburized specimens of various steels not commercially carburized has been frequently carried out as a standard test. For details of this procedure the reader is referred to page 750. The only point to be remembered is that steels indistinguishable in properties and grain size as properly heat treated may possess vast differences in grain size as carburized.

Section-Size Distribution—Inevitably some grains of the mean size, or larger, will be sectioned in such a way as to show a small polygonal surface in the image. Hence an occasional small polygon should not be reported as indicating mixed structure. When, however, a cluster of small grains is found they should be taken into consideration, for it is not possible to section more than about three adjacent large grains to yield small plane grain sections. Generally speaking, in the case

*A most interesting structural feature of carburized steels becomes apparent when they are cooled exactly alike. It has to do with the regularity of the pearlite and the extent to which it fills the envelopes of the grains marked out by proeutectoid carbide and is designated "Normality" or "Abnormality". It is sufficient to note here that this feature is controlled by composition and grain size in the carburized state of steels amenable to the classification. With constant composition, fine grains infallibly favor abnormality, coarse grains favor normality. With constant grain size the normality is then a measure of effective content of deep hardening elements in solution, these elements favoring normality.

of a uniform grain size, about three-fourths of the field will show "grains" within one grain size bracket. Most of the remaining quarter of the field will be made up of the next smaller size with a few still smaller polygons.

Austenitic Grain Size from Fracture—In the introduction mention was made that a correlation of the properties of hardened steel had early been made with the coarseness or fineness of the fracture surface of a break on the hardened steel. As early as 1926 this relationship was used as a quantitative measure of certain aspects of steel quality at the Uddeholm Steel Works in Sweden. At first only five recognized grades of fracture were employed, but later the work was extended through the supervision of Jernkontoret, and in 1927 a 10-step scale was recommended as a suitable measure of tool steel quality; sets of standard fractures in 22 mm. square bars were made up under the direction of Dr. Ragnar Arpl. These bars covered the full range of coarseness and fineness, usually encountered, by steps which to the eye appeared evenly spaced.

In America also, B. F. Shepherd employed an examination of hardenability and fracture appearance as a measure of the probable suitability of steels for certain purposes. Shepherd prepared a set of graded standard fractures in which the entire cross section of the standard bars was hardened. To gain an adequate

Fig. 15—Relation between fracture rating and the true prior austenitic grain size in hardened and broken specimens.

impression of different bars of steel he generally hardened the specimens (of definite section) from four heating temperatures, 1450°, 1500°, 1550°, and 1600°F., and secured thereby a pattern for the coarsening of the steel at increasing temperatures. The fracture was compared with the series of standards similar indeed to the Swedish standards. The latest standard fractures (hardened throughout in both cases) of Shepherd and Jernkontoret, numbered serially 1-10, each as compared with the other, are shown in Fig. 14. For most practical purposes they may be regarded as the same.

It will have become almost obvious by this time that there is a marked degree of parallelism, more than purely fortuitous, between coarseness of fracture and the austenitic grain size which existed in the fracture specimen before it was quenched and broken. This relationship proves to be closer than was at first supposed. The estimation of a great many fractures shows that the relationship between the Shepherd or Jernkontoret fracture numbers and the austenitic grain size responsible for the fracture appearance is about as shown in Fig. 15. It should be borne in

mind that the eye is able to arrive at a mean value of the coarseness of a fracture and that for correlating fracture number with austenitic grain size the mean value of the latter should be used. Thus if a specimen were accurately rated 65% No. 6 and 35% No. 4, then its mean grain size would be about 5.3 and it would exhibit a fracture about midway between 5 and 6. There is one interesting fact about estimating prior austenite grain size by fracture. The eye is more *sensitive* to slight changes in fracture appearance than is the corresponding mean grain size estimation on the microscope. Experienced observers of fractures will agree within one-half, and often within one-quarter, of a single step in the fracture series. There is probably no urgent need even for as many steps as exist in either the A.S.T.M. grain size rating or the fracture rating. The properties which are reflected by grain size are not sufficiently modified by small changes to warrant great accuracy in reporting grain size either by fracture or by microscopic examination.

A word should be said about the fracture appearance from mixed grain sizes. Actually there will be large facets mixed with the fine on the fracture surface but the eye does not once recognize this unless the fracture is fairly coarse; instead, undue influence is exerted by the few coarse facets. Nevertheless an experienced observer can pick out "duplexed" specimens reliably from fracture appearance once he acquaints himself with a few known specimens of mixed grain size. (The mixed grains must really have existed at the time of quenching, and not have been found only after some other unrelated heating.) A few rare anomalous cases are found in which considerable experience is necessary to estimate actual grain size from fracture. The most notable of these is the case of an austenite grain which at elevated temperature coarsens abnormally, having been inhibited until high temperature is reached. The surface of each grain is slightly matte, not brilliant, suggesting a fine grain size, while the large grain size is also apparent from a faint appearance of large facets. The explanation⁵ for this condition has been suggested and occurs too rarely to be serious.

It is easy and practical to combine a hardenability test with the grain size evaluation by fracture as has been done by Shepherd. A standard specimen size must then be adopted and rigidly maintained and the fracture grain size estimated upon the fully hardened or martensitic rim. The depth of this rim can be measured (by 64ths of an in. in Shepherd's technique) after it is rendered visible by etching. Shepherd reports eight numbers which largely classify certain grades of carbon steel as to their suitability for hardened parts. The first four numbers are depths of hardened zone in 64ths of an in. as quenched from 1450°, 1500°, 1550°, and 1600°F., respectively, while the second four numbers are the fracture numbers (Shepherd or Jernkontoret scale) of the hardened zone of the same specimens. It should be stressed that the information secured by this P-F (P = penetration of hardened structure; F = fracture rating) test goes far toward giving a full account of the nature of carbon steel. Obviously alloy steels may harden throughout such large sections that the hardenability feature is inapplicable; the fracture grain estimation is still valid, however.

The most rapid examination of a steel for significant grain size characteristics consists of first rating the fracture*; if it is not indicative of mixed grain size the A.S.T.M. grain size may be reported at once, or if the fracture shows the probability of such a condition it may be polished, etched, and rated microscopically by the charts of Fig. 1-8, inclusive.

Summary—The grain size established in the austenite of a bar of steel ready to be cooled or quenched plays an important part in determining the properties secured. This grain size is generally fine at ordinary quenching temperatures but coarser at higher temperatures, namely, normalizing temperature, or higher.

It is not altered by the method of cooling, hence its estimation may be made upon any suitably heated specimen cooled in just such a manner as to reveal the grain size in the transformed microstructure.

The cooling schedule for best grain size estimation depends upon the steel composition. Either hypo- or hypereutectoid steels may be cooled slowly enough during the first part of the transformation to cause proeutectoid ferrite or carbide

*Austenitic grain size by fracture rating may not be reliable unless the fracture is in a hardened specimen broken without substantial attendant deformation.

to be rejected in the grain boundaries as a thin network. Eutectoid carbon steels have the grain boundaries nicely marked out by black etching fine pearlite (nodular troostite) in the zone not quite fully hardened. Or in any fully hardened steel a special etch may be given the polished specimen to differentiate by selective attack the separate original austenite grains now converted to martensite.

A close approximate estimate of austenitic grain size in any hardened steel may be made by examining its fracture surface. A chart showing approximate relation between austenitic grain size and either Shepherd or Jernkontoret standard fracture number is included.

Eutectoid or hypereutectoid carbon steels (and even hypoeutectoid alloy steels), usually retain considerable undissolved carbide at low temperatures employed for hardening by best practice. Such austenites are fine grained and are somewhat difficult of estimation as to actual grain size. This is of no serious moment since they are obviously fine and since the carbide-ferrite interface has all the influences upon hardening characteristics that grain boundaries exert.

The grain size to which the interest principally attaches is that established in the temperature range of the operation to be carried out and correlated with grain size effects. The estimation of grain size upon regular pieces heated according to commercial operations up to the time of cooling or quenching is therefore recommended.

Case Depth Measurement

By R. B. Schenck*

The following discussion of case depth measurement is intended to apply to the more important forms of case hardening and includes cases produced by carburizing, cyaniding, nitriding, combined carburizing and nitriding and by flame hardening and induction hardening.

Case depth is usually determined either by direct measurement or by chemical analysis. Other methods are sometimes employed in special applications, but are of minor importance and will not be discussed in detail.

1. Direct Measurement—This method in its various modifications is the one in most common use and is applicable to any type of case in the hardened state. It is also applicable, with certain limitations, to unhardened cases where a difference in composition distinguishes the case from the core.

All cases, regardless of the method by which they are produced, consist of at least two zones. Three zones are frequently present, such as the hypereutectoid, the eutectoid and the hypoeutectoid zones of carburized steel. This latter is the transition zone in which the hardness of the case decreases to that of the core, or in which the composition of the case approaches and finally becomes the same as that of the core. This transition zone is always present regardless of the process employed and frequently blends into the core so gradually that no sharp line of demarcation can be observed. The usual practice in direct measurement is to measure from the outer edge of the case to the line where the transition zone ends, estimating as accurately as possible in cases where the "end point" is indistinct.

The accuracy of measurement as determined by the distinctness of this "end point" is influenced by a number of factors, such as composition of core, composition of case, previous heat treatment, and method of preparing the sample. Differences in the quenching temperature and the degree of hardening may influence appreciably the apparent case depth. A possible source of error is in the angle at which the specimen is sectioned. It is extremely important that the measurement be made along a line normal to the outer surface of the case.

The several methods in general use employing direct measurement are as follows:

A—Scale Measurement of Rough Fracture—This may be performed either with the unaided eye using a suitably graduated steel scale (preferably in hundredths of an inch), or by means of a low power (10 to 15X) microscope containing a suitable scale. A Brinell microscope answers the purpose admirably. The fractured surface may be either untouched, blued, or etched before measurement. This method applies only to cases in the hardened state.

Untouched fractures can be measured with fair accuracy when the core hardness is sufficiently low to provide good contrast between case and core. Hard cores usually require coloring by either bluing or etching.

Bluing offers an effective method for producing the required contrast. Any means of heating which will develop the necessary temper colors may be employed, such as a lead bath, sand bath, hot plate or tempering oven. An excellent method is to immerse part of the sample in molten lead (1200-1500°F.) leaving the fractured surface exposed to the air. As soon as the color appears the piece is removed from the lead and held until the blue tint deepens on the case area. The sample is then quenched in water to arrest further color change and withdrawn while still warm so that the surface will immediately dry.

Etching is used extensively and produces good results when properly applied. Cold nital is the usual reagent.

B—Scale Measurement of Rough Polished Cross Section—This method employs the same technique as that described under 1-A with the exception that the uncolored surface offers no contrast and must be either blued or etched. Etching is generally preferred for rough polished sections and bluing for rough fractures. Although approximate results can be obtained on unhardened cases, the use of this method is generally confined to cases in the hardened state.

C—Scale Measurement of Highly Polished Cross Section Using High Power Microscope—This is essentially a laboratory method and requires trained personnel. Magnifications of 100X using an eyepiece equipped with a scale graduated in thou-

Prepared for the Subcommittee on Carburizing. The Membership of the Subcommittee was as follows: R. B. Schenck, Chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

sandths of an inch are usually found suitable for a wide variety of work. As an etching reagent, cold nital will generally answer most requirements.

This method provides greater accuracy than either 1-A or 1-B especially where it is desired to measure the individual zones, or where it is difficult to develop the necessary contrasts as frequently occurs with certain compositions and treatments. Both hardened and unhardened cases can be measured with a high degree of accuracy.

2. Chemical Analysis—In this method successive layers are machined from the surface and subjected to chemical analysis. It applies only where the case is machinable and different in composition from the core, such as work which has been slowly cooled after carburizing or cyaniding. This is strictly a laboratory method and is slow and costly. Its greatest value is in research work.

The following are additional methods which have only limited application and are seldom used:

3. File or drill through the core at right angles to the case until the hardness of the case resists further cutting or abrasion. Measurement of the remaining hard case is taken as the depth. The case on one side must be removed by grinding in order to expose the core. This method is subject to many variables chief among which is the personal equation.

4. Weigh the parts before and after case hardening. This, of course, does not apply to induction or flame hardening. From the increase in weight, the approximate case depth can be determined by calculation.

5. Taper or step grind the hardened sample and determine the hardness at various distances below the surface. This gives a rough approximation of the hardness gradient and the depth of case. This method cannot be used satisfactorily for cases below a certain depth, and where applicable, does not give accurate results due to the effect of the underlying softer metal. It can, however, be used as a specification requirement to control the hardness at a given depth, although it is seldom used for this purpose. Its principal use is in research work.

Magnetic Testing*

Magnetic testing ordinarily applies to ferromagnetic materials: Iron, nickel, cobalt, and their alloys. Magnetic testing of materials used principally for their magnetic properties, such as transformer steels and magnet steels, is done under the same general conditions as will be encountered in service. The limitations of electrical equipment are often determined by the magnetic properties of available ferromagnetic materials. The principles and methods of this type of testing may be found in reference No. 1 or in standard works on electrical engineering.

Magnetic Analysis—Magnetic testing is used also to determine the soundness and mechanical properties of ferromagnetic materials. This type of testing usually is distinguished by terming it Magnetic Analysis. There are many magnetic measurements which can be made quickly and easily, without destruction of the material, and which may be used to test all of the material instead of representative samples. Although numerous factors are involved which influence the magnetic measurements, such as variations in analysis, physical properties, structure, stress, and temperature enough progress has been made to provide commercial magnetic tests for a number of applications. The choice of method of magnetic analysis used in any application depends upon which of the several magnetic characteristics show most variation when the desired property varies. The properties of the magnetization curve and the hysteresis loop may be called the d.c. characteristics of the material. The d.c. characteristics include values of the permeability under different conditions of magnetization, various relations of magnetic induction and magnetizing force, the reluctivity relationship, coercive force, and many combinations of the above. In addition to these, alternating current offers a new set of possibilities. By testing at two or more frequencies it is possible to separate hysteresis and eddy current losses. In the alternating current methods the sample forms the core of a transformer. The various characteristics of the core, particularly those of permeability and watt loss values, provide shifts in the phase angle between the current and the voltage of the induced current and give rise to harmonics in the alternating current wave. By suitably measuring the shifts or the harmonics, any differences occurring in the magnetic characteristics of the cores (or samples) can be distinguished.

Direct current methods are preferable if the fundamental magnetic properties are desired; if it is necessary to secure results at high induction values; or if the samples are large in cross section—in which case excessive eddy currents cause heating and the measurements are predominantly influenced by the surface portion of the samples. The use of a direct current is considered preferable for the detection of deep seated mechanical defects.

Alternating current methods find their greatest usefulness in testing for uniformity of analysis, structure and physical properties. Great sensitivity can be obtained and more variables analyzed. They are most suitable for material of uniform cross section.

Since 1918 the A.S.T.M. has had a committee to study and develop magnetic testing.^{4, 7, 11}

Continuity Tests—Flaws and discontinuities cause an abrupt change in the magnetic field, which when the field of force appears outside the surface is known as "leakage flux." Thus a magnetic field may be set up in the piece either by a current passed through it or by an exciting coil or external magnetic circuit. The leakage flux may be detected by a search coil or by iron filings. In the Sperry rail test¹⁰ a heavy direct current is passed through sections of both rails by a car traveling at a speed of about 6 miles per hour. The rail head is explored by a test coil which gives a record of variations in current density in the rail by measuring the variations in the transverse magnetic field induced by the current. The test is sensitive to flaws to an accuracy of 1% of the cross sectional area of the rail head. Although structural changes, such as those caused by wheel burns, also cause variation of the field, a periodic inspection shows the slow enlargement of cracks and locates a great percentage before they become dangerous.

The powder method (Magnaflux) of inspection^{7, 12} is a special form of continuity test which has come into use in the last few years. It detects surface seams,

*This article was prepared by the Subcommittee on Magnetic Testing. The membership of the subcommittee was as follows: James Allison, Chairman; C. T. Hewitt, H. J. Noble, F. H. Allison, and R. R. Moore.

seams immediately below the surface, grinding cracks, quenching cracks, shrinkage cavities in welds, and incipient fatigue cracks in used machinery. The parts to be inspected are first magnetized, either by passing a current (a.c. or d.c.) through them, or by an external yoke. They are then coated with a finely divided iron powder or magnetic iron oxide, wet or dry. This may be done either while the magnetizing force is being applied or after it has been removed leaving only residual magnetization. Due to so many variables, such as current source and magnitude, and the method and time of applying the magnetic powder, a nonuniformity as to the sensitivity in the test exists as well as in the interpretation of results.

Method of Application of Powder—The dry method consists of dusting the powder on, as from a shaker. The wet method applies either in immersing the work in the vehicle containing the magnetic oxide (immersion method) or in flowing the solution over the work (flow method).

Condition of Magnetism while Powder is Applied—When the part is permanently magnetized and only the residual magnetization is utilized the method is referred to as the residual method. If the powder is applied while the current continues to flow through the work, it is known as the continuous method.

The most important phase of the whole inspection procedure is the magnetization of the piece. The magnetic field created must be at right angles to the defect sought. If the defect be parallel to the flux, no indication will appear. As the angularity of the defect with the flux increases from 0-90°, the indication becomes more strongly apparent. For this reason, irregularly shaped parts must be magnetized in several directions and the powder applied after each magnetization, as second magnetization tends to neutralize the first.

Subsurface defects may be located to a certain extent depending upon size, location, depth beneath the surface, condition of material, and the procedure used. A fair approximation is that a defect may be detected when its depth below the surface is about the same as the cross sectional height of the defect. Present equipment, producing as much as 6,000 amperes with the continuous method, will probably exceed this. Defects on the surface are easily identified by a low amperage with any method of application. The greatest problem in this connection is in evaluating the seriousness of the defect, since different currents and methods produce powder patterns of different intensities.

In another important inspection test, used for such parts as turbine rotor wheels, the material to be tested is passed between the poles of a heavy magnet employing a strong direct current field. Search coils mounted in the pole pieces detect changes of magnetic reluctance of the material due to flaws.

Magnetic Comparison Methods—The correlation of magnetic properties with the composition, physical and structural properties presents a much more complicated problem. The permeameter is used to determine the actual values of the several magnetic properties, as found from the normal induction curve and the hysteresis loop. The normal induction, maximum induction, residual induction and coercive force values of pure carbon iron alloys ranging from 0.13-0.96% carbon content, showing the effect of hardening, tempering, and annealing, have been determined by Cheney.² A thorough discussion of the reluctivity relationship from permeameter tests correlating various tempering treatments after oil and water hardening of a 0.85% carbon steel with magnetic properties has been given by Nusbaum, Cheney, and Scott.³ The results of other permeameter tests correlating chemical and physical properties of metals with magnetic tests are given by Burrows,⁴ and Mauer.⁵ In general the coercive force and hysteresis loss increase as the hardness increases, while the permeability, maximum induction and residual induction decrease.

In addition to variables which influence the mechanical properties, the test is sensitive to unequal stress conditions and differences in temperature in the material, which exert little effect upon the mechanical properties. The effect of stress variation is most noticeable when high frequencies or low magnetizing forces are employed. These tests all serve to compare the material with a standard of known mechanical properties, and care must be used to eliminate variables in the magnetic measurements due to unimportant differences in analysis and structure. Direct correlation of chemical, physical or structural properties with magnetic indications have not yet been successfully established, but within one lot of material of the same general composition and treatment, variations from the indications given by the standard may be correlated and laboratory tests on one sample of a group of pieces showing the same variation will establish the properties of that group.

The simplest form of this test, and the earliest in point of commercial application, is an alternating current bridge in which the impedance of a coil surrounding the test specimen is balanced either against a standard specimen in a similar coil or against a synthetic standard of equal impedance. An alternating current galvanometer or an oscillograph with or without amplification may be used to indicate unbalance; or the current may be passed through a rectifier and measured as a direct current. The balanced alternating current method is usually applied to the testing of large quantities of similar materials, such as razor blade stock, wire, bar stock, and tubing. Certain peculiarities of magnetization may be indicative of seams or other unsoundness. This is particularly true in testing cold worked steel for defects, because the strain appears to enhance the magnetic difference between sound and defective areas. A special coil arrangement representing a modification of the balanced alternating current method has been developed which permits a selective investigation with regard to certain mechanical defects. This coil combination suppresses the effect of differences in material, dimensions or stresses and emphasizes the effect of mechanical flaws such as surface cracks and seams. Analyses and heat treatment variations are now carried out by direct analysis of the emf. induced by the test material. The basic principle used in these measurements represents a modernization of the Joubert¹⁵ point contact method using electronic switching devices and direct current compensation for accurate wave form determinations. Splendid results have been obtained with these apparatus in locating flaws and in determining slight variations in analyses as well as uniformity of heat treatment.

Similar apparatus with special methods of magnetization is used in testing races, balls, and rollers in the ball bearing industry. If the magnetic readings are interpreted in terms of Rockwell hardness variation, reliable average measurements can be made to one-tenth of one Rockwell division. The magnetic indications show irregular internal stress conditions independent of the surface hardness, also variations in microstructure, cracks, soft spots, and shallow hardness.

In certain fields, particularly for small parts of magnetic material, high frequency magnetization is used and a number of types of oscillating circuits have been devised which give valuable indications of slight changes in composition and heat treatment. Tests of this type can also be applied to nonmagnetic materials, measuring in this case the electrical resistivity.

Two specimens having like magnetic properties will have like mechanical properties, but the converse is not necessarily true. Much work has been done, and much remains to be done, to correlate the structural and mechanical properties with resultant magnetic characteristics. The relation between magnetic and other properties is complicated so often by a multiplicity of factors, such as simultaneous variations in chemical composition, heat treatment, mechanical strains, and flaws, that each application must be worked out independently and the testing procedure must be coordinated carefully with mechanical tests.

The Spark Test

By W. G. Hildorf¹ and C. H. McCollam²

General—The spark test is a method for the classification of steels, according to their chemical analysis, by visual examination of the sparks which are thrown off when the steels are held against a high speed grinding wheel. The test is valuable as a safeguard against the accidental mixing of steels of different analyses, or as a method for separating steels known to be mixed. Spark testing is fast, convenient, economical, and, when applied with proper regard for its limitations, reliable and accurate.

Spark testing is essentially a method for the separation of steels having different analyses. It is not a substitute for chemical analysis, and is not intended for the identification of "unknown" samples. The character of sparks should be similar when spark streams are examined from a number of samples supposedly of the same material. Should one or more of the samples exhibit a spark stream of different character, the presence of "foreign" material is indicated. Chemical analysis can be used in such cases for positive identification.

One of the advantages of the spark test is that it can be applied to steels in practically all stages of production, whether as the billet, as bar stock in the racks, as partly machined forgings, or even in many cases as finished parts. As spark testing is done directly on the pieces themselves, expensive sampling methods with attendant possibilities of mix-ups in numbering and handling are avoided. Small pieces of mixed material which could not be sampled, even if the cost of analysis were not prohibitive, are frequently salvaged, quite economically, by the spark test.

Theory—When a piece of steel is held in contact with a moving emery wheel, small particles of the metal are torn loose. With a high speed wheel, this tearing process is so rapid that the temperature of the particles is raised to incandescence. As they are hurled through the air the trajectory is quite easily followed, particularly against a dark background. This trajectory is called a "carrier line." If the metal is either ingot iron or wrought iron, the result is a small sheaf of single lines, termed a "spark picture." If a piece of carbon steel of about 0.20% carbon is held in contact with the wheel, there will be noted a lightening of the color of the line, and the presence of a number of short single "forks" or "primary bursts," which are due to the presence of carbon (Fig. 1).

While a spark is incandescent and in contact with the oxygen of the air, the carbon present in the particle is burned to carbon dioxide. The transition of solid carbon to gaseous carbon dioxide is accompanied by an increase in volume. Although the particle of hot steel is plastic, it offers resistance to this volume increase, thus building up an internal pressure that is relieved only by an explosion of the particle. There are some observations to support this explanation of the "bursts." For instance, the examination of the incandescent particles when they are cold reveals in the residue numerous hollow spheres with one end completely blown away. The relation of carbon content to the frequency of "bursts" also marks carbon as the element responsible for the forking of the carrier line. A 0.20% carbon steel exhibits a slight forking effect (Fig. 1); a 0.40% carbon steel, a pronounced burst (Fig. 2); and steel in the neighborhood of 1.00% carbon, a minute explosion (Fig. 3). Moreover, greater intensity of bursting is noticed as the carbon content of the steel is increased.

Examination of the Spark Stream—The technique of the visual examination of the spark stream is quite important. When it is properly done, variations in the stream become more readily distinguishable.

Wheel Pressure for Spark Testing—When using the spark cabinet, which will be described later, the operator should hold the pieces on the wheel in such a manner as to throw the spark stream about 12 in. in length horizontally and at a right angle to his line of vision. It is well at this point to spend a little time determining just the right pressure required to maintain a stream of about this length without reducing the speed for most efficient performance of the wheel. Wheel pressure is an important item, whether the piece be held against the wheel, as in cabinet work, or vice versa, because increasing the pressure will raise the

¹Metallurgical Engineer, and ²Chief Chemist, The Timken Steel & Tube Co., Canton, Ohio.

temperature of the spark stream and bursts, and will give the appearance to the inexperienced eye of a higher carbon content. Experience will later dictate to the trained spark tester the length and volume of the spark stream required for the various steels that will be encountered.

Having determined the proper wheel pressure, it is suggested for the introductory tests that the operator select two steels of widely different carbon content, preferably plain carbon steels. An S.A.E. 1020 and 1050 or higher carbon will do very well. First one, then the other should be held against the wheel, always being careful to strike the same portion of the wheel with each piece. With eyes focused on a point about $\frac{1}{2}$ the distance from the tail end of the stream, watching only those sparks which cross the line of vision, it will be found that after a little while a mental image of the individual spark will be formed. After an operator can fix spark images in this manner he is prepared to examine the character of the "spark picture."

Sections of Sparks—

The entire sheaf of sparks may be divided into three equal sections:

1. The wheel sparks, which are the third of the stream nearest the wheel.
2. The center area.
3. The tail sparks, which represent the third of the stream farthest from the wheel.

The components which are to be observed are the carrier lines, the spark bursts and the "characteristic sparks." The carrier lines will vary in length, breadth, color, and number. The spark bursts will vary in intensity, size, number, shape, and distance from the wheel or from the end of the carrier lines. Carrier lines are the incandescent streaks that trace the trajectory of every glowing particle. They are discussed more fully in connection with the characteristic sparks to which they are closely related.

The Spark Burst—The spark burst, that is, the "carbon spark," is the most useful characteristic of the spark picture, since the variations in the number and intensity of the bursts indicate the changes in the carbon content. Steels alloyed

Fig. 3—S.A.E. 1095 Steel, C 1.00%, showing intensity of bursts in the higher carbon range.

Fig. 4—S.A.E. 4615 Steel, C 0.15, Mo 1.75, Ni 1.75, showing a detached "Spear Head" which is characteristic of Molybdenum and the swelling in the spark line indicating Ni with Mo.

differently but with the same carbon content are not always so easily identified. Most of the alloying elements have some influence on the spark picture. They may affect the carrier lines, the bursts, or the form of characteristic sparks. Their effect may be, for example, to retard or to accelerate the carbon spark, or to make the carrier line lighter or darker.

Effect of Molybdenum—The burst is the characteristic spark of carbon. Other elements have distinctive characters. One of the most easily recognized of all the characteristic sparks is that of molybdenum, which appears as an orange colored spear point on the end of every carrier line. Other features of the molybdenum spark are that the spear points are detached from the carrier lines, and that they are always present regardless of the length of the lines (Fig. 4). Sometimes, when the carbon content is high, the spear point is difficult to distinguish; but if a decarburized surface can be found, the characteristic spark immediately becomes quite distinct.

Effect of Nickel—Nickel gives a characteristic spark, identified as tiny blocks of brilliant white light. In low carbon steels (0.10-0.20% carbon and 3.5-5% nickel) these blocks are located in the spark stream quite near the wheel, but in higher carbon steels they are located in the burst. When present with molybdenum, nickel partly suppresses the carbon spark.

Effect of Silicon—Silicon suppresses the carbon spark to a more marked degree.

The carrier line from silicon steels of the S.A.E. 92 series is much shorter than from a plain carbon steel of the same carbon content, and generally ends abruptly in a white flash of light.

Effect of Tungsten—The spark streams for 18-4-1 and molybdenum high speed steels as shown in Fig. 5 and 6 were prepared by J. V. Emmons. He states that, "18-4-2 high speed steel sparks the same as the 18-4-1 type. With light wheel pressure, 4% tungsten steel is similar in appearance to 18-4-1, but with heavy pressure the 4% grade shows an occasional secondary burst not found in the 18% tungsten type. Observations are based on a 9 in. alundum wheel, grade 46M, 1750 r.p.m."

Fig. 5—18-4-1 high speed steel. Red color with numerous red lines.

Fig. 6—Molybdenum high speed steel. Red and orange with numerous orange spearheads with trace of primary bursts.

Equipment for the Spark Test

The Spark Cabinet—A cabinet makes possible the examination of spark streams under ideal conditions. It is convenient both in training men for spark testing and in the examination of spark streams from steels with spark characteristics which are unknown to the operator.

A substantial wood cabinet, about 40 in. long, 36 in. wide, and 36 in. deep will be quite suitable for this purpose. The cabinet should be placed on a bench or table at convenient height for the operator. The inside should be stained a flat black. The interior should have means of artificial illumination. The location of the spark cabinet should be such that no direct light will strike either the operator's eyes or the inside of the cabinet.

The grinder may be mounted in the left front of the cabinet, and should throw a spark stream across the front of the cabinet at right angles to the operator's line of vision.

The Grinder—If the spark stream is to be satisfactory for examination, a spark test grinder should have a peripheral wheel speed of not less than 3500 ft. per min.

If light grinds are to be made on parts in production, the grinding wheels should be of small diameter. If the operator is not to be handicapped by unnecessary fatigue, the weight, bulk, and balance of the grinder are important considerations. Portable grinding equipment of approximately 7 lb. with the weight well distributed has been found very satisfactory. The shaft bearings should be readily replaceable.

The grinding wheels should be rather coarse and very hard and approximately $1\frac{1}{4} \times \frac{3}{8} \times \frac{1}{4}$ in. in size.

Spark Test Goggles—Eye protection during spark testing is very important, both in avoiding injury from steel and emery particles, and in minimizing the

effects of certain light rays. Goggles which satisfy these requirements have been developed for spark testing by some of the optical companies.

Standard Spark Test Samples—Standard samples can be prepared from bar steel. A convenient size is 1 in. in dia. and 3 in. long. One end should be stamped with the identification marking of the steel and a sample number. Chemical analyses of these samples should be kept for reference. Samples should cover as wide a range of chemical compositions as possible, to permit the operator to familiarize himself with the manner in which the character of sparks is affected by various carbon contents and alloying elements.

For training purposes, a dozen or more samples should be cut from bars of the material with which the spark tester will have occasion to do most of his work. For example, if experience in identifying the molybdenum spark is desired, a dozen pieces of S.A.E. 1020 in 1 in. round steel, stamped "1," and a dozen pieces of S.A.E. 4615 of like size and appearance, stamped "2," will provide the standard samples necessary. These standard samples are consulted only as a means of verifying the correctness of the classification of the "unknown" samples.

Spark Testing Personnel—Thought should be given to the selection of personnel for spark testing. It is advisable to select a man whose eyes are light sensitive and whose manner is alert. He should have a fair knowledge of the composition of various steels.

The operator should be given every opportunity to practice spark testing. Given the necessary physical and mental attributes, a spark tester's efficiency becomes a matter of experience in the examination of sparks. The more rapidly that experience is acquired, the sooner he will be available for duty.

In connection with spark testing personnel, it is advisable to have strict supervision of the work. The spark tester should be held at his highest possible efficiency. It must be understood by each operator that his work must be 100%, that not a single piece of foreign steel can be passed in error. Decisions must occasionally be made as to when the spark test can be used safely, and also when it definitely must not be used. The reputation of the spark test for reliability will depend largely upon the wisdom of such decisions.

Plant Spark Testing—Proper lighting conditions are a very necessary adjunct to satisfactory spark testing.

The presence of strong direct light, either natural or artificial, is a distinct disadvantage. Spark testing should be done in a shadow, and against a dark background.

It is advisable to protect the spark stream from heavy drafts of air as this will cause a very definite hooking of the tail sparks, which may be confusing.

Bar and tube stock, carefully racked, can frequently be spark tested without removing from the racks. Similar material in bundles can be spread out on inspection benches. Small pieces of regular size and shape are generally placed on work benches. If a large number of pieces must be tested in a limited time, laborers can be used to arrange the parts in uniform rows for the spark tester, so that his time can be applied entirely to spark examination.

Care must be exercised in the case of hot rolled or heavily scaled material to be certain that the spark stream is not from a decarburized area. Bar stock is more safely ground on the cut end, and forgings at the point from which the tonghold was removed.

The Bessemer Process of Steel Making*

By Dr. G. B. Waterhouse

History—The invention of the Bessemer process of steel making was a great event in the world's economic history. Up to that time steel was scarce and expensive, being made chiefly by the crucible process. It was reserved for special purposes so wrought iron, cast iron, and bronze were used for structures, engines, and ordnance. Henry Bessemer developed the process in the search for an improved material for guns. He started his experiments late in Dec., 1854, shortly before his 42nd birthday. The first public description of the process was in Aug., 1856, before it had been perfected. Many difficulties were afterward encountered principally due to phosphorus in the pig iron used as the raw material.

Application for a patent disclosed that William Kelly had worked on a similar method since 1847 and a patent was granted to Kelly in 1857. The patent controversy was ended in 1865 after which time developments were rapid, mainly due to the energy and genius of the great engineer, Alexander Lyman Holley.

Description of Bessemer Converter—Molten blast furnace iron (pig iron) of the proper composition is poured into the Bessemer converter, which is a pear

A Bessemer blow.

shaped steel vessel mounted on trunnions. The converter is tilted to receive the metal. The charge varies from 5-30 tons. The lining of the converter is of acid refractory material, the slags produced consist of more than 50% silica so the process is known in this country as the "acid Bessemer." When the vessel is charged, air is admitted from the blowing engines or turbo-blowers through one of the trunnions, which is hollow, to a blast box at the bottom of the converter. From this box the air passes through numerous holes or tuyeres, $\frac{1}{2}$ - $\frac{3}{4}$ in. dia., to the interior of the converter. The blast pressure is about 20 psi. These converters are known as bottom blown, and this article will not describe the process carried out in side-blown converters used in foundries for making steel for castings. These vessels are

often called baby Bessemer (Tropenas Converters) and usually vary from $\frac{1}{2}$ -3 tons.

Operation of Bessemer Converter—After the blast is turned on the vessel is slowly turned upright. The air blows through the charge and oxidizes (in the order given) the silicon, manganese, and carbon. The combustion of these materials, especially silicon, and some of the iron furnishes the heat to carry on the process. The progress of the operation is shown by the flame issuing from the mouth of the converter. At first the flame is short and dry with very little visibility, followed by a reddish-brown flame of low luminosity occurring during the

*Prepared for the Subcommittee on Melting by Dr. G. B. Waterhouse, Mass. Institute of Technology, Cambridge, Mass.

The personnel of the Subcommittee on Melting was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Herty, Jr., O. K. Parmiter, and Dr. G. B. Waterhouse.

period of silicon and manganese oxidation. Then as the carbon burns it changes in character and increases in size. It becomes yellowish-white and reaches about 30 ft. in height. When the flame drops, which it does in a characteristic way at the end of the blow, the vessel is again turned down on its side and the blast shut off.

This whole operation or "blow" usually takes from 12-18 min. The material is now known as "blown metal." It contains traces of silicon and manganese and 0.06% or less of carbon. Substantially all the phosphorus and sulphur of the original pig iron are present in the blown metal which also contains about 0.2% of oxide of iron, FeO . This last constituent makes the metal red short, incapable of being successfully forged or rolled, so that some deoxidizing agent is added to the blown metal. When making soft or low carbon steel the usual addition is ferro-manganese. This is crushed to egg size and added to the blown metal while it is being poured from the converter into the ladle, after which the ladle is swung or carried over the ingot molds and the ingots poured. The final soft steel would show about 0.08% carbon, 0.38% manganese, 0.10% phosphorus, 0.045% sulphur and traces of silicon. The whole operation is brief and the liquid pig iron is very rapidly converted into liquid steel.

Raw Material for Converters—The main raw material is liquid pig iron. This is usually brought from the blast furnace or furnaces in ladles and poured for storage into containers known as mixers, because various casts are mixed or averaged. These mixers hold from 200 to as much as 1200 tons. They are of steel construction, lined with fire brick or other refractory material and can be rotated by electricity or hydraulic power. Metal is poured from the mixers when needed through a spout into a ladle standing on a scale. When necessary, the mixers are heated by means of gas, oil, or tar. The heat supplied is just about enough to offset radiation losses. Care is taken to prevent blast furnace slag entering the mixers with the iron, as it would cause slopping and bad working in the Bessemer converter.

The composition and amount of iron entering the mixer is very important to the Bessemer blower. For good practice the pig iron is held within fairly close limits.

Silicon is the most important element and varies from about 1.00-1.80%. It should be held as constant as possible and at the particular amount found to work best for the individual shop.

The total carbon does not vary much in iron for the Bessemer converter. It is not reported usually and varies from about 3.80-4.00%.

The manganese usually runs under 0.60%. It should not run much higher as high manganese makes a thin slag in the converter which slops out of the vessel on to the floor of the shop and causes trouble, as well as loss of steel, and handicaps the blower in producing steel of given analysis.

Phosphorus in the iron varies from about 0.085-0.100%. Substantially all of the phosphorus in the pig iron remains in the blown metal and in the finished steel. It must be low enough so that the final steel is not above the required amount which in general is 0.110%, although some specifications allow a maximum phosphorus content of 0.13%. This is the reason why iron ores are classed as Bessemer and Non-Bessemer, the Bessemer ores being so low in phosphorus that the blast furnace iron made from them is low enough to be used in making Bessemer steel. Incidentally all the phosphorus entering the blast furnace with the charge is reduced and enters the liquid iron.

The sulphur usually runs about 0.04% and varies from 0.03-0.08%. Both phosphorus and sulphur are about 8% higher in the finished steel than in the blast furnace iron, due to loss in weight and concentration.

Bessemer Losses—In ordering the proper weight of liquid iron from the mixer to make a heat of steel the blower allows for the weight of scrap he will use and the loss in weight during blowing. This loss in weight is fairly constant, depending on various factors, chiefly the composition of the iron, because silicon, manganese, and carbon are practically all oxidized together with a certain amount of iron. The loss is usually from 8-10%.

Temperature Control—After the liquid iron has been poured into the vessel, the blast turned on and the vessel turned upright, the scrap chute is swung into the nose of the vessel and the correct amount of scrap added. This scrap addition

is a method of temperature control, which is the most important part of a blower's duty.

The finished steel in the ladle must be at the proper temperature for the grade of steel being made. It must pour cleanly from the ladle into the ingot molds so that the ingots will set properly. If too cold a large skull will be left in the ladle and there may be trouble in pouring the ingots. If too hot the internal structure of the ingots will not be correct and surface as well as interior defects may develop during rolling.

In general, the blower tries to control his temperature so that a small skull is left in the ladle after pouring the finished steel. There are two methods available to him to reduce temperature. One is by the addition of scrap, the other is by using steam admitted with the air. Bloom butts, or crop ends of steel weighing about 100 lb. are generally used, but sometimes cold pig iron is employed. Only about 15% by weight of the liquid iron can be used, so the Bessemer is not a scrap-using process.

The composition of the liquid iron is generally maintained to give a reserve of temperature, so scrap or steam is generally needed. Occasionally cold heats are encountered. If known in time ferrosilicon can be added with the liquid pig iron, or added down the scrap chute, or the vessel can be blown on its side so that part of the air rushes over the surface of the metal. This causes excessive loss of iron, but does raise the temperature.

Additions—In making most of the steels listed in Table I ferromanganese is added while the blown metal is being poured into the ladle. This brings about deoxidation and adds the required amounts of carbon and manganese to give good rolling and working properties and meet the specifications. There is a loss of manganese during this operation of about 35%. This loss is allowed for and experience soon shows the correct weight of ferromanganese to be added. The sulphur needed for the free cutting steels is added to the converter in the form of pyrites or to the converter or ladle as stick sulphur in a strong paper bag. There is a loss of about 45% of the sulphur added.

In the case of the higher carbon steels the proper weight of liquid iron is brought from the mixer and added to the blown metal in the converter. Many times the blast is turned on and the vessel is turned up and down again to give a "puff" and thoroughly mix the materials, then ferromanganese is added as usual while being poured into the ladle. Sometimes the required carbon is obtained by adding dry crushed anthracite or coke in bags to the blown metal while being poured from the converter.

Rail steel, and other high carbon steels, were formerly made by adding a molten mixture of spiegeleisen and pig iron to the blown metal in the converter. This mixture was first melted in cupolas and carefully calculated to take care of losses. The requisite amount of carbon, manganese, and silicon, was added and the correct weight was tapped from the cupolas. Almost any grade of carbon steel can be made by the Bessemer process, if the use of steel high in phosphorus can be allowed.

Composition of Bessemer Steel—During the first part of the blow, silicon and manganese are rapidly oxidized and enter the slag. This is characterized by a short dry flame. The flame then turns to a yellowish-white as the carbon is oxidized and begins to increase in size until it is 25-30 ft. in height. At the end of the blow there is a well marked drop of the flame and the vessel is turned down. The heat may be turned down green or it may be "full blown," depending on the steel to be made.

The blown metal contains from about 0.04-0.10% carbon, traces of manganese and silicon, phosphorus from about 0.085-0.110%, and sulphur about 0.03-0.07%, except in cases where sulphur has been added in the vessel. The additions required to make the finished steel are added usually in the ladle or else in the vessel and in the ladle.

Typical analyses of finished steel are shown in Table I.

Table I does not include bars, small structural shapes, and materials for railroad purposes, such as spikes, bolts, and nuts, for which considerable Bessemer steel is used. The analysis of steels for these purposes does not vary greatly from

Table I
Composition of Bessemer Steel

Material	Carbon %	Manganese %	Phosphorus %	Sulphur %
Soft Bessemer Steel Grades				
Skelp	0.10 max.	0.30-0.60	0.11 max.	0.08 max.
Sheet and tin bar	0.10 max.	0.30-0.50	0.11 max.	0.07 max.
Soft wire	0.08	0.30 max.	0.11 max.	0.08 max.
Medium wire	0.08-0.12	0.30-0.50	0.11 max.	0.08 max.
Hard wire	0.12-0.17	0.70-1.00	0.11 max.	0.08 max.
Ordinary screw stock	0.08-0.13	0.70-1.00	0.09-0.13	0.10 min.
A.S.T.M. screw				
S.A.E. 1112/stock	0.08-0.16	0.60-0.90	0.09-0.13	0.10-0.20
Special Grades Screw Stock				
Special	0.08-0.16	0.75-1.10	0.09-0.13	0.20-0.30
High carbon screw stock	0.25-0.35	0.60-0.90	0.09-0.13	0.075 min
Reinforcing Bars				
Reinforcing bars	0.15-0.35	0.70 max.	0.11 max.	0.08 max.

that shown for skelp and sheet bar except that as a rule only the phosphorus is specified and tensile test requirements are imposed. In many of these steels, especially those exposed to atmospheric corrosion, copper is present from 0.20-0.30%, and has been found to be very helpful.

Application—The main uses of Bessemer steel are indicated in Table I. They include skelp for making lap welded and butt welded pipe, especially the smaller sizes, sheet bar for rolling into sheet for tin plate and galvanized material, bars and special shapes for free machining purposes, especially automatic screw machine products and wire products of many different kinds. The Bessemer process is the second steel making method of the country in regard to tonnage. Its capacity is about 11.5% of the total steel making capacity and for the last few years the steel made by this process has varied from 11.5-12.8% of the total steel made. It has shown a declining tendency until recently, being 33% in 1912 and dropping to 11.6% in 1931 and increasing somewhat since that time.

Also considerable steel is made by a combination of the acid Bessemer and the basic open hearth process, which is called the Duplex Process, the steel being known and shipped as open hearth steel. One other application of the Bessemer process is the Aston process of making wrought iron.

The Open Hearth Process*

By Dr. C. H. Herty, Jr.

Origin of the Open Hearth—The first steel made in any considerable quantity was produced by the crucible process, invented by Huntsman in 1740. Puddling furnaces were patented in England by Cort in 1784 and Great Britain rapidly took the lead in iron making. Bituminous coal was used in these furnaces.

In 1855, Sir Henry Bessemer patented the Bessemer pneumatic process for manufacturing steel, and in 1856 Dr. C. W. Siemens and his brother Frederick obtained patents on a regenerative furnace. These two patents were destined to revolutionize the steel world, the former by enormously increasing steel tonnage and the latter by providing for temperatures so high and so constant that the tonnage from regenerative furnaces at present far surpasses that produced by the Bessemer process.

In 1864, Martin successfully operated, with the assistance of Dr. Siemens, a regenerative furnace for melting steel. The open hearth process as developed by these gentlemen was called the Siemens-Martin process and the fundamentals of their process are in common use today. It must be stated that the open hearth process did not originate with Martin or Siemens, as J. M. Heath in 1845 proposed this method. His attempt failed as the necessary temperature could not be obtained.

Henderson in 1870 and Snelus in 1872 suggested the use of lime as a dephosphorizer for iron, and Thomas and Gilchrist in 1877 used a basic lining in a Bessemer converter. Basic linings were put into use in open hearth furnaces and the process at once came into favor. In the acid open hearth process, referred to later, neither phosphorus nor sulphur may be eliminated; this process is therefore confined to the melting of raw materials low in these two elements.

The Basic Open Hearth

The Necessity for Refining Pig Iron—Pig iron as produced today for the basic open hearth process has the following approximate percentage composition: C, 4.00; Mn, 1.70; P, 0.25; S, 0.04; Si, 1.00; Fe, 93.00.

As this material is unfitted to fill the needs for which steel is used, it must be refined. Refining consists of the removal of carbon, manganese, phosphorus and silicon by oxidation and the removal of suspended oxide material and gases by scrubbing. It is necessary to supply a strong base which will form stable compounds with the oxides of phosphorus and silicon and with sulphur and hold these permanently in the slag—which is the molten magma formed when the lime and various oxides unite with or dissolve in one another.

The Open Hearth Furnace—Figs. 1 and 2 show in cross section a sketch of an open hearth furnace. The basic furnace consists mainly of a shallow, elliptical shaped vessel lined with some suitable basic refractory. This hearth is covered with a silica roof forming a combustion chamber, and the steel is made on the hearth of the furnace. Suitable spaces are left for doors on one side of the furnace through which the operations may be controlled.

The hearth is usually lined with magnesite brick and covered with a mixture of burned magnesite or dolomite and open hearth slag. The bottom may be kept in repair with dolomite or in extreme cases with ground magnesite or chromium ore. The average consumption of dolomite for repairing is about 35 lb. per ton of steel.

In many modern furnaces the backwall slopes at an angle instead of being built straight as in Fig. 1. This sloping backwall prolongs the life of the furnace as the flame cannot cut the brick as readily as it can with the straight backwall; the construction also facilitates repairs.

In the rear of the furnace, at the center and bottom of the hearth, is the tap hole. This is between 4 and 8 in. in dia., depending upon the size of the furnace and type of practice. During the steel making period this hole is filled with a suitable refractory material which may be easily removed when the heat of steel is to be tapped. In a tilting furnace the tap hole is put in above the level of slag and metal and the furnace tilted when it is desired to withdraw the metal.

*Prepared for the Subcommittee on Melting by Dr. C. H. Herty, Jr., Research Metallurgist, Bethlehem Steel Co., Bethlehem, Pa. The personnel of the subcommittee was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Herty, Jr., O. K. Parmiter, and Dr. G. B. Waterhouse.

Open hearth furnaces are usually of the regenerative type, in which the hot gases are passed through checker chambers and transfer heat to the brickwork. From time to time, say every 15-20 min., the flow of gases through the furnace is reversed and cold air enters the hot chambers and is heated to about 2400°F., which promotes fuel economy and temperature control.

Some fuels are preheated in the checkers before they enter the furnace, others are not. The fuels preheated are producer gas, and mixtures of blast-furnace and coke oven gas. Tar and oil are brought directly to the port and atomized with high pressure steam or air. They are preheated to about 300°F. to increase the fluidity for atomization. Natural gas and coke oven gas are delivered to the port direct. The port must be designed differently for each type of fuel.

Charging the Furnace—The scrap, cold pig iron, limestone, and ore are loaded into charging boxes. A charging machine picks up the individual boxes and charges the contents on the hearth of the furnace. In a charge consisting of limestone and scrap, the limestone is placed on the hearth first, followed by the scrap, until the charging is completed or the furnace is full. If large amounts of light scrap are being charged, it is often necessary to fill the furnace, melt down the scrap somewhat, and then finish charging the scrap. It is sometimes advisable to charge a layer of scrap on the hearth of the furnace before charging the limestone, particularly if the limestone tends to stick to the hearth too much. If ore is charged, it is generally added before the limestone or just after the limestone, depending on the condition of the bottom. Charging ore first tends to cut out the bottom. When cold pig iron is used, it is usually charged after the scrap. If hot metal (molten pig iron) is used, and the largest tonnage of steel is made by this method, it is brought to the furnace in a ladle and poured through a spout inserted in one of the charging doors. The hot metal addition is made after the scrap has melted down somewhat and after the furnace has become well heated.

The analysis of the steel scrap should be known because copper, nickel, and molybdenum can be diluted but not eliminated from the metal. Tin, zinc, lead, and antimony are detrimental to the quality of the steel, and so should be avoided.

Melting the Charge—During the period between the charging of the scrap and the hot metal addition, there are two chemical reactions taking place in the bath: (1) The oxidation of the scrap while it is melting; and (2) the calcination of part of

Fig. 1—Typical open hearth furnace.

the limestone. As soon as the hot metal is added, a great deal of the scrap and all of the limestone are submerged in liquid metal. The oxidation of the exposed scrap proceeds until sufficient scrap has melted to raise the level of the liquid

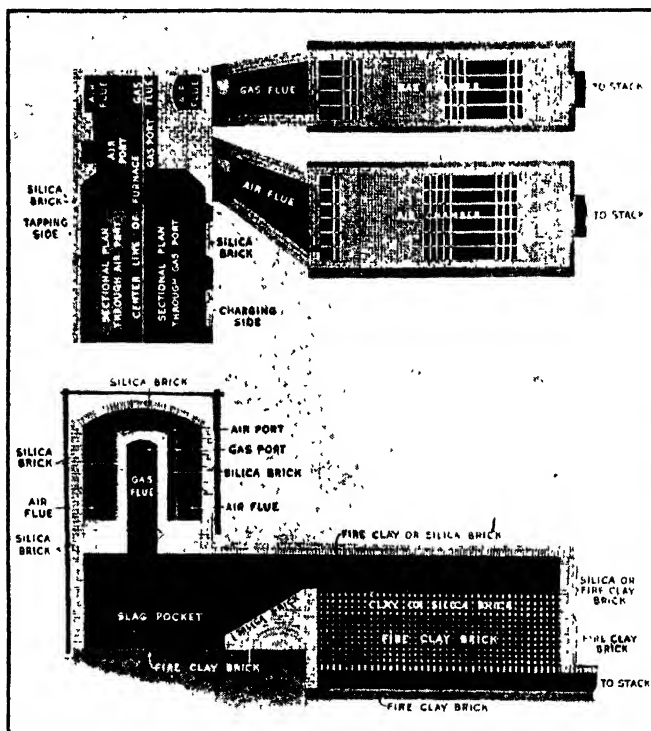

Fig. 2—Typical open hearth furnace.

metal enough to cover up all solid material. During this melting period large amounts of carbon dioxide are being evolved from the calcination of the limestone by the reaction:

There is a heavy boiling action caused by the CO_2 evolution, and at the same time this gas reacts with the liquid iron to form iron oxide.

As the scrap continues melting, pieces of limestone which have been held on the bottom by the scrap begin to rise through the metal bath and float in the slag. The period in which the lime is coming up is known as the lime boil, and the agitation from the gas evolution assists materially in the transfer of heat from the fuel to the bath because the hot upper layer of metal is thoroughly mixed with the colder lower layers.

Function of Slag in the Steel Making Process—As it is necessary to remove carbon, manganese, phosphorus, and silicon as oxides, and in order to prevent phosphorus from reverting from the slag into the metal during the latter stages of refining, it is necessary to carry a large percentage of lime in the slag to form a stable calcium phosphate. The slag floats on the surface of the bath, and it is through the iron oxide content of the slag that a large amount of the removal of metalloids (C, Mn, P, Si) by oxidation is carried out. The slag thus acts as a regulator of oxidation and as a carrier of undesirable impurities. If the slag is weakly basic, considerable erosion of the furnace lining will take place. If

the slag is too basic it is generally very viscous and the reactions taking place will be slowed up considerably. From the best data available at the present time, the slag is evidently calcium silicate, $\text{CaO} \cdot \text{SiO}_2$, and $2\text{CaO} \cdot \text{S} \cdot \text{O}_2$, containing dissolved CaO , $3\text{CaO} \cdot \text{P}_2\text{O}_5$, MnO , FeO , CaS and CaSO_4 . The magnesia in open hearth slags is generally held to be suspended as periclase (MgO), in which some iron oxide may be dissolved.

It is very desirable that the slag have a given consistency during the working period, as the oxidation of the bath is controlled not only by the amount of iron oxide in the slag, but also by the rate at which iron oxide diffuses from the slag into the metal, and this diffusion rate is a function of slag viscosity. If the slag is too viscous it may be thinned out by the addition of fluorspar, and if the slag is too thin (too fluid) it may be thickened (made more viscous) by additions of burnt lime or burnt dolomite.

The Formation of the First Slag—During the initial melting period, a large amount of iron oxide is formed by the oxidation of the scrap. This combines with some of the calcined limestone on the hearth of the furnace and with some of the dolomite on the banks to form a slag high in iron oxide and lime. As soon as the hot metal is added, the slag formed during melting reacts with the metalloids in the pig iron, and silicon and manganese are very rapidly eliminated. The result of the reaction of these two metalloids with the iron oxide in the slag is a sharp decrease in the iron oxide content of the slag and a rapid increase of SiO_2 and MnO in the slag. These slags are weakly basic, and the result is a severe erosion of the furnace banks by this initial slag. If high silicon pig is used this corrosive action is intensified. If the pig iron used is unusually high in phosphorus a tilting furnace is used, so that slags may be readily drawn off.

The composition of the slag at the time the heat is melted has a very pronounced effect on its oxidizing power during the finishing period of the heat. The reason for this is that a great deal of the oxidation takes place through the action of the furnace gases on the FeO in the slag, and the higher the FeO in the liquid slag the greater will be the oxidation throughout the heat.

Working the Heat—After the heat is melted a test is taken out of the furnace and the carbon content estimated by the appearance of the fracture. From this fracture the furnace operator judges how much ore should be added to eliminate the carbon to the desired point. The ore is introduced either by shoveling or in a charging box, and a lively reaction at once proceeds because of oxidation of the carbon. As the carbon is being eliminated, steel tests are sent to the laboratory for carbon analysis, or the operator estimates the carbon content of the bath by a fracture test. While the carbon is being eliminated, the operator attempts to "shape up" his slag so that at the finishing period the slag is of a creamy consistency and the metal at the proper temperature. The temperature of the bath is judged by stirring a rod through the heat and noting the appearance of the end of the rod when it is withdrawn from the furnace, or by pouring a test and noting the tendency of a skull (solidified crust) to form in the spoon, and also by noting the fluidity and nature of the steel while pouring. The temperature of the bath is regulated by the amount of fuel used, and this is generally under the control of the operator. If the amount of fuel used is kept constant, the temperature of the bath will be influenced by: (1) The amount and viscosity of the slag; (2) the degree of agitation; and (3) the chemical reactions in the bath, which may or may not influence the second factor. All of these factors are to some degree under the control of the operator and must be considered in securing the desired bath temperature. In some of the newer installations of open hearth furnaces the fuel regulation is determined by automatic control of checker temperatures, thus eliminating to a large extent the personal element in the judgment or misjudgment of steel temperature.

Finishing the Heat—Unfortunately, during the process of elimination of metalloids by oxidation, a considerable amount of iron oxide dissolves in the steel bath, and before the steel can be poured into the molds it is necessary to either partially or fully deoxidize the steel. This deoxidation is carried out either in the furnace, the ladle, or the molds. For so-called quality steel, as much deoxidation as possible is done in the furnace, because the elimination of nonmetallic matter resulting from deoxidation depends to a considerable extent on the distance the inclusion must rise before leaving the metal. Inasmuch as the average depth of the steel bath is about 30 in. and the average height of a ladle about 12 ft. it is obvious that if

the deoxidation is done in the furnace less time will be required for the elimination of nonmetallic matter than if the deoxidation is carried out in the ladle. On the other hand, when the steel is deoxidized in the furnace, if the heat is held in the furnace to allow nonmetallic matter to rise out of the steel, iron oxide will diffuse from the slag into the steel.

Inasmuch as the slag-metal area in the furnace is much greater than in the ladle, it is evident that more iron oxide will diffuse back from the slag in the furnace than from the slag in the ladle. There is, therefore, a balance between deoxidation in the furnace and ladle, but by properly regulating the viscosity of slag and its iron oxide content, it has been found that it is better to deoxidize in the furnace than in the ladle. Some deoxidizing additions must be made in the ladle on account of the oxidizing conditions in the furnace. Thus, if a heat is being deoxidized with ferromanganese and ferrosilicon, it is customary to add ferromanganese in the furnace and ferrosilicon in the ladle. The choice of deoxidizers and the manner of deoxidation are extremely important in making the best steel from a given open hearth heat at the time the steel is ready to be deoxidized. In some cases the steel is deoxidized in the mold, but this is generally a poor practice for making high quality steel. For certain types of steels where the specifications, particularly for cleanliness, are not rigid, this practice is very satisfactory in that it is by far the cheapest of any deoxidation method. In general, aluminum is the only deoxidizer used in the molds. Ferrosilicon is used in some grades of steel, but this is the exception rather than the rule.

The time consumed in making a 100 ton heat of open hearth steel is about 11 hr. and is divided as shown in Table I.

Killed, Semikilled, and Rimmed Steels—From the standpoint of the user, there are three classes of plain carbon steels with which he must deal: (1) Killed steel; (2) semikilled steel; and (3) rimmed steel. All forging grade steels and in general all steels above 0.25% carbon are killed. Structural steels from 0.15-0.25% carbon are killed or semikilled, and most steels below 0.15% carbon are rimmed.

Killed Steel—In forging grade and other high carbon steels, the essential quality of the steel is soundness (freedom from blowholes and segregation), because this material generally goes into a product where definite strength factors are desirable. The term "killed" indicates that the steel has been deoxidized sufficiently so that the metal when poured into an ingot mold lies perfectly quiet. In killed steel there is no evolution of gas, and the top surface of the ingot solidifies almost immediately. This condition is brought about through the proper additions of ferrosilicon, aluminum, and other strong deoxidizers.

In making killed steels general practice is to catch the heat coming down—that is, to eliminate the carbon to the desired analysis and then tap the heat. It is preferable to leave the heat in the furnace for at least 10-20 min. after the addition of the deoxidizer, as this length of time is necessary to insure proper mixing of the furnace additions and elimination of nonmetallic matter.

Semikilled Steel—In making semikilled steels the heat is caught coming down at the desired carbon content, and the manganese is added either in the furnace

Table I
Division of Time for Making 100 Ton Open Hearth Heat
Total Time, 11 Hr.

Operation	% of Time
Start of charge to end of charging.....	19.0
Actual time spent in charging.....	6.0
Start of charge to hot metal addition.....	35.0

^cFor killed steel.

or in the ladle. If silicon is used, it is added in the ladle as 50% ferrosilicon. When aluminum is used it is sometimes added in the molds, although in most plants additions of aluminum are made both in the ladle and in the molds.

Rimming Steel—Clean low carbon deoxidized steels are very difficult and costly to make in the basic open hearth so recourse is had to the process called rimming in which the steel is partially deoxidized with manganese, either alone or with some other deoxidizer. When the metal begins to solidify there is a brisk evolution of gas which cleanses the surfaces of the growing crystals. The result is a skin of very clean metal. The depth of this skin varies with the skill of the steel maker. When the metal has cooled to the point where solidification proceeds throughout the liquid a great deal of the gas is trapped and a porous interior results. In making rimmed steel the effort of the steel maker is to obtain the proper rimming action in the molds, as this rimming action determines to a large extent the solidity of the surface of the ingot. This rimming action is obtained by a close control over the iron oxide content of the slag, the slag viscosity, the temperature at which the heat is poured, and the deoxidizers used.

The advantage of the rimming steel practice is that the outside surface of the ingot is quite clean and low in carbon. These factors give an excellent surface to the finished product. A wide variety of steels for deep drawing, where ease of forming is the major consideration, are made by the rimming process.

The Acid Open Hearth Process—In the acid open hearth process the lining of the furnace is of silica sand, an acid material. As any basic material in the slag would tend to attack the lining rapidly, the acid process is confined to materials low in sulphur and phosphorus as these two elements require the presence of lime for their elimination.

In an acid slag a large part of the iron oxide is combined with silica as silicate of iron and manganese. This combined iron oxide will not diffuse into the metal, nor will it be oxidized readily by the furnace gases. Therefore, for a given total iron oxide in the slag, the metal will be much less oxidized in the acid open hearth furnace than in the basic open hearth furnace, and consequently there will be fewer products of deoxidation to be removed.

One of the most important advantages of the acid process over the basic is the fact that the composition and nature of the slag can be controlled almost at will.

A typical acid slag analysis in per cent is: FeO, 15; MnO, 21; SiO₂, 53; CaO, 4; and small amounts of Al₂O₃, Cr₂O₃ et cetera. The per cent of FeO + MnO is automatically regulated by the fact that iron manganese silicates will dissolve up to about 60% of SiO₂ from the furnace banks. By regulating the amount of MnO in the slag the FeO can be closely controlled. Thus the operator is enabled to control more consistently the quality of the steel being made.

The acid open hearth process is used almost entirely for the manufacture of killed steel. A very small tonnage of rimmed steel is made by this process.

The Melting of Tool and Other High Grade Steels in the Basic Electric Furnace

By J. P. Gill*

History—The first attempt on record to melt steel electrically dates back to 1878 when Siemens conducted his initial experiments with arc melting in a small crucible. During the next 20 years progress in electric melting was slow, and probably the most noteworthy event in this period was the development by Heroult about the year 1890 of a furnace for the production of ferroalloys. Beginning with the year 1900, the development of electric furnaces gained momentum, and several types of both arc and induction furnaces were placed on the market. The most promising one of these was the so-called direct arc type devised by Heroult and finally put into production in this country about 1906. Consequently the history of electric melting of tool and other high grade steels in the United States dates back only about two decades.

The first furnaces were relatively crude affairs, but both the mechanical and electrical features were greatly improved and perfected during the following ten

years, and the introduction of automatic control, modifications to facilitate charging, improvements in electrodes, increase in power input, and finally the introduction of multi-voltage transformers have made the arc furnace an entirely practical tool. Along with the development of the furnace has come the development of improved melting practice. Originally the electric furnace was designed to make tool steels and special alloys which were then made by the crucible process, but its field rapidly broadened to fill the need of new requirements in special ordnance steels and automotive alloy steels.

Fig. 1—Electric melting furnace.

There followed naturally a further development of the process along economic lines, resulting in a diversity of practice, such as the cold melt process used in the manufacture of tool steels and the finer alloys, and the hot metal, or duplex process, often used in tonnage electric practice.

There is consequently a considerable difference in melting practice between the different units of the tool and alloy steel industry, and it would be an impossible task to give here more than a general outline of the subject.

Description of Furnace—Of the many principles originally employed to melt steel electrically, it appears that only the system employed first by Heroult has stood the test of time. In this system the steel in the furnace forms the common conductor for the current flowing between the electrodes which enter the furnace through the roof. Fig. 1 shows a vertical section of a six ton furnace of this type. The tilting mechanism, the electrode control motor, and the switchboard control

*Prepared for the Subcommittee on Melting by J. P. Gill, Metallurgist, Vanadium-Alloys Steel Co., Latrobe, Pa. The membership of the subcommittee was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Hertig, Jr., O. K. Parmiter, and Dr. G. B. Waterhouse.

apparatus are often installed in separate rooms, a practice which affords protection from dirt and from the danger of heats burning through the bottom into the pit.

Current is supplied from a suitable source through the bus bars F and electrode holders G to the electrodes which are three in number, arranged in the form of a triangle. Electrodes may be either graphite or amorphous carbon. Arcs are sprung from the electrodes to the bath K, thus heating the metal both by direct conduction from the arc, and by radiation from the roof and walls. The height of the electrodes above the bath, and consequently the heat input, is controlled automatically by the winch motors H which raise and lower the electrodes.

The furnace proper consists of a cylindrical steel shell lined with refractories as indicated in the legend. The roof is detachable. The furnace is tilted about the stationary axis or trunnion E placed directly under the spout J. The tilting mechanism consists in a motor A which raises the furnace by means of the connecting rod D operated through a series of gears B. The weight of the furnace is balanced by the counterweight C.

The choice of refractories for the basic electric furnace is a very important consideration. The hearth itself must be a basic material, such as magnesite or burned dolomite, to withstand the lime slags used in the basic process. The walls and roof on the other hand need not be of basic material, but must be capable of withstanding extremely high temperatures. Silica brick is used almost exclusively for this purpose.

The hearth is either rammed in by layers, using a suitable binder such as sodium silicate, molasses, or tar, and is then burned in as a whole, or else the bottom material, often mixed with a suitable flux such as an oxide basic open hearth slag, is shoveled into the hot furnace and burned in layer by layer. This is done by the heat of electric arcs formed between the furnace electrodes and other electrodes placed across the hearth of the furnace.

Electric furnace refractories are subjected to severe service. The arches, jambs, and door brick especially have a short life, which can be lengthened by the use of water cooled doors and frames. Protection of refractories by water cooling shows up to better advantage on the larger furnaces.

The tonnage capacities in which commercial units of this type of electric furnace are built, together with the transformer capacities, are as follows:

Furnace Capacity, Tons	Transformer Capacity, kva.
1	1,000-1,200
3	2,000-3,000
6	3,000-4,000
15	4,000-7,000
25	7,500-10,000
40	12,000-13,500
100	20,000-25,000

All sizes except the 100 ton have three electrodes on the one three-phase circuit, while the 100 ton furnace has 6 electrodes with the two three-phase circuits.

The tendency is toward higher voltages during the melting down period—voltages which run as high as 250 for some furnaces. During the refining period, the voltages may be as low as 85-100. Switches are usually provided so that two or three voltages are possible at the will of the operator, and so that it is possible to have as many as 12 steps.

General Description of Process—In brief the process consists of charging into the hearth of the furnace a known weight of scrap of suitable physical and chemical character, and melting this down as quickly as possible. When the charge is melted, it is the usual practice to add a quantity of burned lime with some fluorspar or sand to act as fluxes, which together with the oxides resulting from the melting of the scrap form a highly oxidized basic slag. It is sometimes the practice to accomplish this same end by the addition of limestone to the charge. The procedure from this point depends upon whether or not it is desired to dephosphorize. If the scrap is of such a character that removal of phosphorus is not necessary, the slag is at once turned over, that is, whitened or deoxidized by the additions of crushed coke or ferrosilicon. If it is desirable to remove phosphorus, the furnace is tilted slightly and the black phosphorus-bearing slag is raked off or "pulled," a new slag of lime

fluorspar and coke or ferrosilicon made up, and the process continued as in the first case.

The description thus far applies to the so-called cold melt process. In the manufacture of tonnage steels it is sometimes the practice to duplex from a basic open hearth furnace, that is, to tap steel from the open hearth furnace where it has been dephosphorized, into the electric furnace, where it is to be given an ultimate refining under a deoxidizing slag. This is known as the hot metal process. As in the case of the cold melt process, a new slag is built up, and the process continued as in the case of the regular practice. The new slag is carefully treated with further additions of coke and other reducing agents until many of the gases and oxides resulting from the melt down, together with most of the sulphur, are eliminated from the metal. In the case of alloy steels the necessary alloy additions to bring the bath within the specified limits of composition are made during this period. Final deoxidation is accomplished in the furnace with the use of ferrosilicon and ferromanganese, the temperature properly adjusted, and the heat tapped into the ladle. In some cases final additions of aluminum or other deoxidizers are made to the ladle. The spout of the furnace is usually equipped with a skimmer, designed in such a manner as to allow the metal to flow from the furnace free from slag. The slag finally runs out after the ladle has been filled. After remaining in the ladle a sufficient length of time to allow any entrapped slag to rise to the top, the metal is poured or teemed into molds.

At intervals during the melting process, samples of the bath are taken for quick chemical analysis, so that chemical composition is known at all stages of the process, which enables the melter to make the necessary composition adjustments with carbon or ferroalloys.

With this brief outline of the process completed, the various stages will now be taken up more in detail.

Selection of Raw Material and Method of Charging (Cold Melt Process)—The bulk of the charge usually consists of selected steel scrap of such a composition that upon melting down, the bath will contain a smaller percentage of the various elements than is required in the final steel. This obviously allows for proper final adjustment with ferroalloys and carbon additions. Of equal importance is the physical condition of the charge, its thermal and electrical conductivity, and its distribution in the furnace. All of these factors have a bearing upon the economy of furnace operation. Consequently, considerable care is exercised in obtaining the proper balance between heavy and light scrap, in properly distributing these, and in distributing any other materials used in the charge, such as ore, scale and certain ferroalloys.

The Melt Down—The melting down of the charge is usually conducted at as high a voltage as possible so as to melt quickly, thus increasing furnace economy and decreasing melting losses. To accomplish this, and also to allow the later operation to be carried on at a lower voltage, most furnaces are now equipped with variable voltage transformers. For the first 15 or 20 min. of melting, the electrodes "search," that is, rise and lower as they melt through the scrap charge, and the current through the furnace fluctuates widely. This action stops, however, as soon as a pool of metal has formed under the electrode. When this pool has reached an appreciable size, the melter starts pushing the unmelted scrap toward the center of the furnace, cleaning off the banks, and gradually working all loose scrap into the bath. As soon as this is accomplished, the first slag additions are made, consisting usually of burned lime with a small quantity of fluorspar as a flux.

Refining—The refining stage in the electric melting process is of utmost importance, since it provides one of the big advantages which the electric furnace has over the open hearth. In the open hearth furnace, the process is essentially an oxidizing one because of the oxygen introduced in burning the fuel. In the electric furnace, on the other hand, the atmosphere can be controlled at will, with the result that the steel may be thoroughly deoxidized in the furnace.

The refining operation in the electric furnace may be considered as beginning with the formation of the slag, although as a matter of fact refining begins with the melting of the charge and continues over a certain period after complete melting. These operations are based largely upon reactions between the steel and the slag, which are confined to the contact surface of the two materials. They are also based upon reactions taking place within the steel itself between

certain of its original constituents and others that may have been added for the purpose, and finally upon reactions within the slag.

The outstanding feature of this slag is its basic character, meaning that its basic constituents, the most important of which is CaO , must prevail over its acid components, the chief representative of which is SiO_2 . This is necessary for the preservation of the basic furnace lining and also because the prevalence of CaO is necessary for bringing about most of the desired reactions.

These reactions aim to accomplish three distinctly different purposes, and since they would conflict with each other in several ways, they must be carried out separately and in a fixed sequence.

Removal of Oxidizable Elements, Principally Carbon and Phosphorus, But Sometimes Also Manganese and Chromium, By Oxidation—This process is carried out by the addition of an oxidizing agent to the slag, usually iron oxide. If it is intended to remove the carbon, the oxide is added in the form of scale or iron ore after the temperature of the bath has been raised as much as possible. At low temperatures it is possible to oxidize the other elements without burning out all the carbon. If phosphorus, manganese, or chromium are to be removed, it is necessary to pull the resulting black slag, since these elements are held only in a highly oxidized slag. If, as sometimes happens in the melting of alloy steels, only the carbon has to be lowered, the slag is not pulled, but the oxides of alloying elements that may have accumulated in it during the oxidation of the carbon are reduced back to the metallic state, and return to the steel.

Reduction of Oxides in the Slag—This comprises the oxides of all metals reducible by either carbon or silicon. Such oxides may have been formed unintentionally during the melting of the steel or intentionally as described above, or they may have been added for the purpose of direct reduction, or they may be continuously formed in the slag because of loosening of particles of hearth and patch material that pass through the steel and into the slag.

This deoxidation of the slag may be carried out by the use of finely divided carbonaceous material such as coal or coke, by calcium carbide, or by a metallic reducing agent such as ferrosilicon. This white refining slag usually contains enough calcium carbide so that the odor of gas is noticed when the slag is cooled in water, but it should not be too carbidic. The slag may be maintained in this condition throughout the refining period.

During the refining under the white slag, it is desirable to have the slag come in contact with the metal as much as possible to facilitate the removal of oxides and nonmetallic inclusions. Stirring the bath at intervals during this period is, therefore, helpful.

The Deoxidation of the Steel—This consists in the conversion of those oxides that are soluble in the steel, namely, FeO and CO , into insoluble ones, such as SiO_2 , Al_2O_3 , and CaO , and their separation from the metal by gravity. This separation is greatly facilitated if, instead of forming a highly infusible oxide such as SiO_2 , we attempt to form at the same time several such oxides, which through combination with each other become fusible slags. The finely divided slag particles will then coalesce into larger globules and separate themselves from the metal more easily. For this reason the final deoxidation of the steel is sometimes carried out by the addition of a so-called "double" deoxidizer, such as calcium silicide or aluminum-silicon alloys.

Desulphurization of the bath also takes place with the deoxidation of slag and steel, the sulphur combined with manganese rising to the surface of the bath, where it reacts with the CaO (lime) content of the slag to form calcium sulphide, which is absorbed and held by the white basic slag.

The presence of a deoxidizing agent in the slag during the final period is desirable. There is only one such agent that can exist in the slag, namely, calcium carbide. It must be kept in mind, however, that this carbide has practically no deoxidizing effect upon the steel. It will reduce oxides of iron, chromium, manganese, tungsten, or vanadium which have risen into the slag, but it has little effect, if any, upon oxides suspended or dissolved in the steel. It is, therefore, of no conceivable advantage to hold the steel for a great length of time under a strongly carbidic slag. Some steels require more time than others, but for high quality steels a holding period of about two hours under the white slag appears

to accomplish the desired results. No time longer than this has shown any special benefit.

Composition Adjustments—Beginning at the time the bath is first melted clean, and continuing through the refining period, occasional spoon tests are poured and sent to the laboratory for chemical analysis. Quick determinations upon these tests enable the melter to make what additions are necessary to bring the final composition of the heat within specified limits.

Additions of metallic elements are usually made in the form of ferroalloys, the exact composition of which is known. The charge should be so adjusted that the carbon content of the bath, when melted down, is lower than the final desired carbon. After slagging off, carbon additions of 10 or more points are best made by working in over the bare metal a definite amount of crushed electrode or some such carbonaceous material of known carbon content. The power may be turned off and the electrodes submerged, but the use of the crushed carbonaceous material is more certain. When only a few points of carbon are to be added, the addition of wash metal, low phosphorus pig iron, or carbon briquettes is very satisfactory.

Close and constant co-operation between the laboratory and the melting floor is necessary if narrow chemical limits are to be maintained.

Temperature Adjustment—Having brought the bath to the required chemical composition by refining operations and by the use of necessary additions, a number of spoon tests are next taken to determine its temperature and, as far as possible, its condition with regard to the progress of deoxidation. On straight carbon and some alloy steels, it is possible to determine the proper temperature by the so-called film test, which consists in taking a sample in a well slagged spoon and noting the time required for a film to freeze over the surface of the steel. With many alloy steels this is not possible and the temperature is determined by pouring the steel from a well slagged spoon in a uniform stream into a little test mold. No frozen metal should remain in the spoon and the test piece cast should have smooth sides without wrinkles. The top surface of this test piece gives also some indications as to the progress of the deoxidation, at least as far as the presence or absence of soluble oxides is concerned. It should be smooth and free from eruptions and slightly depressed in the center.

Tapping and Pouring—The heat of steel, now of proper composition and temperature and properly deoxidized or killed, is ready to tap into the ladle. This operation, as well as the final pouring, is carried on with the greatest care. The ladle, of the bottom pour type, having been properly dried, is brought up to the furnace and hung under the spout. The furnace is then slowly tilted into the tapping position, and the metal allowed to flow in a steady stream into the ladle. The exact practice employed in tapping varies in different plants. Some operators tap through a runner brick walled into the spout, thus holding back the slag until the tap is complete. Others prefer to tap slag and metal together. Temperatures are often taken with the optical pyrometer during tapping for record, and for the guidance of the melter. Usually no deoxidizers are added to the ladle, although occasionally small additions of aluminum may be made to counteract the tendency toward oxidation during the tap.

In pouring the ingots, the ladle is sometimes rested in a carriage which travels over the line of molds, but usually it is suspended directly upon the ladle crane. The principal precautions in pouring are to properly regulate the pouring rate and the character of the stream so as to pour with a minimum of splashing in the mold, thus insuring a good ingot surface. Soundness of the ingots and freedom from shrinkage cavities is insured by proper mold design, consisting in heavier walls near the bottom of the mold and in a chamber gradually widening toward the top, and by application of the so-called "hot top." This usually consists of a refractory form placed on top of the mold, acting as a reservoir of molten metal, from which the ingot is continuously fed until completely solidified.

Acid Electric Steel

By Fred Grotts*

History—The origin of acid electric steel probably begins with the development of the Heroult electric furnace in 1890. Previous to this, there was much experimental and production work done in the making of alloys in electric arc furnaces with both acid and basic linings.

Like other acid steel melting processes, acid electric practice is based on lining the furnace with silica brick, resulting in the usual acid slag reactions. The acid electric furnace was the result of an endeavor to increase the tonnage obtained from the original crucible process of making steel, which is essentially a remelting procedure, there being little or no opportunity to eliminate sulphur and phosphorus.

During the war period of 1914-1916 increased attention was given to the acid practice due to inability to obtain magnesite for the basic lining necessary in basic furnaces, the chief source of supply at that time being Austria. This helped to develop the acid method.

Application—The acid electric process, while not commonly used for making ingots, is adapted to the manufacture of steel castings for several reasons. The

Fig. 1—Typical bricking diagram for electric furnace.

melting time is distinctly shorter than in basic practice because of the necessity in the latter practice of making such additions as are necessary to reduce the amount of sulphur and phosphorus. High temperatures are obtainable without undue reaction with the refractories which keeps such costs at a minimum. Good fluidity is also obtainable which is always desirable in producing castings. The slag, as will be described later, is also easily handled, an important item especially in lip pouring and in cases where steel with minimum slag inclusions is the objective. Many machine shops often specify acid steel for castings with machined surfaces, since it seems to be general experience that the surface of acid steel castings is superior from the standpoint of cleanness and uniformity.

Description of Furnace—The furnace consists essentially of a round steel shell lined with suitable refractories to withstand high temperatures generated by the carbon or graphite electrodes. Fig. 1 shows the method of lining in order to get the acid reaction necessary for the process. The contrast with a basic lining is also shown. The furnace is mounted on a tilting device, which is operated by electric controls. This arrangement is utilized for pouring the molten steel into ladles or other receptacles. It is recommended that the controls be placed so that the metal flow can be observed. Other electrical controls should be conveniently placed, but well protected from dirt and molten metal.

The general construction of furnaces varies considerably. In some cases the roof is detachable, in which case charging buckets carried by overhead cranes are used. These buckets are built with bottoms that open mechanically permitting the charge to be placed conveniently in the furnace.

Some furnaces have permanent tops but with side doors for charging. This arrangement permits the accurate placing of the charge, but the process is slow

*President, Fort Pitt Steel Casting Co., McKeesport, Pa. Prepared for the subcommittee on melting. The membership of the subcommittee was as follows: G. V. Luerssen, chairman, G. A. Dornin, J. P. Gill, Dr. C. H. Hertz, Jr., O. K. Parmiter, and Dr. G. B. Waterhouse.

and requires more time and labor than furnaces with a removable top. Both types of furnaces have their desirable features and existing conditions sometimes call for either one or the other. Some furnaces have special tap holes which permit the holding back of slag, which procedure is usually desirable. Atmospheric control should always be kept in mind in any furnace construction.

The heat is applied to the charge by means of the arcs formed by the electrodes contacting the material, and is controlled by the height of the electrodes above the bath, or by variable voltages or taps. It is customary to use the higher voltages for melting and the lower voltage for refining. Several foundries melt down at 130-140 volts and refine at 90-110 volts; others melt down at about 200 volts and step down to about 100 volts for refining. The details of the equipment used are determined largely by the requirements of the particular practice used.

Selection of Material—The material for the charge consists of foundry return scrap, gates, heads, and risers to as much as 50 or 60% of the total, although it may be less according to the desires of the melter and the scrap available. The balance of the charge consists of plate and turnings or punchings. It is not considered good practice by some metallurgists to use too much rusty scrap on account of the possibility of gas contamination.

The acid process at present has practically no action on the sulphur and phosphorus content; therefore the materials of the charge must be as low as possible in these elements. Some operators charge the fine materials first to form a compact mass in order to minimize the tendency to form a hot pool of metal below the electrodes, while others place their plate scrap on the bottom. Too much sand on the return scrap, or too high silicon content sometimes requires higher melt down temperatures.

Charging Material—A successful procedure for a 2 ton furnace consists in scattering uniformly over the bottom about 700 lb. of plate scrap (15% approx.), 3200 lb. of returns (60% approx.), 300 lb. of flashings (5% approx.), and 1100 lb. punchings and turnings (20% approx.) for a furnace charge of 5200 lb. This charge is calculated to contain about 0.30% carbon, 0.75% manganese and 0.35% silicon. The estimated amount of iron ore, is 250 lb. which is considered sufficient to take the carbon down to below 0.10% and the silicon to about 0.05% and the manganese to about 0.10%.

The plate is charged first, then the returns, and the fines last to fill in the spaces. In some cases part of the plate may be placed on top. Some melters add ore or mill scale to the charge, while others add the oxide when a puddle has formed below the electrodes, followed by other additions as the melt proceeds.

Some observations indicate that cracked castings result from high return scrap in which case it is desirable to change to a virgin charge of purchased scrap, or else cut the returns to 15 or 20%.

Melting Operation—Melting down is carried out at high voltages, usually between 140 and 200, the exact procedure depending upon the equipment and the established practice in the particular plant. The melting operation is essentially an oxidizing procedure which gives rise to a rather violent boiling action, according to the reaction $C + FeO \rightarrow Fe + CO$ most of the iron oxide (FeO) is supplied by the ore added to the charge. The carbon is reduced rapidly from an approximate 0.30% in the charge to about 0.18% at the melt down. The boil is continued until the carbon drops to about 0.10% or less and then silicon and manganese lower still. If the original ore addition is not sufficient to lower these elements to the desired percentage, boiling should be continued by means of further oxide additions. When carbon, manganese, and silicon are "down," further oxidation is stopped, or in other words, the bath is "quieted" by an addition of low silicon pig. Some shops however prefer to let the ore boil itself out, in which case no pig is added. The slag at this stage is quite black.

In lieu of the practice just described, some melters and metallurgists prefer to "catch their heats coming down." For instance, if the charge is figured at 0.30% carbon and it is desired to finish at about 0.20% carbon, they "kill" the heat at that point with ferrosilicon or ferromanganese, rather than boil the carbon out to a low point such as 0.08% or 0.09%, necessitating later building up to the required final analysis by carbon addition.

Refining—In the boiling operation, some of the ore combines with the silicon to form silica, according to the reaction $Si + 2FeO \rightarrow SiO_2 + Fe$.

This SiO_2 is eliminated by the continued agitation of the bath, together with some manganese oxide, which is likewise formed by the addition of the ore resulting

from the reaction $\text{Mn} + \text{FeO} \rightarrow \text{MnO} + \text{Fe}$. The SiO_2 and MnO , formed are suspended in the steel temporarily, but combine quickly with the excess FeO forming iron and manganese silicates which rise into the slag. In this connection it is important to add sufficient ore or scale to almost completely oxidize the silicon, and to form fusible silicates which separate readily from the bath. The excess ore is also necessary in order to flux any sand adhering to the scrap as well as silica resulting from the erosion of the furnace lining. It might be repeated here that 250-300 lb. of ore gives a satisfactory result for a 5500 lb. charge as described.

Slag—The slag formed in the oxidizing stage of the heat is thin and rich in iron oxide, and there is a constant tendency toward equilibrium between the slag and molten metal. Some melters recommend considerable quantities of lime in melting. Such practice, however, will result in high erosion of the furnace lining with corresponding high pollution of the metal.

After the oxidizing boil has been quieted or allowed to work out, the next step is to bring the slag into condition. A satisfactory practice consists of adding about 3 shovels of dry, used molding sand and about one shovel of burned lime (CaO). Some melters use limestone (CaCO_3) which accomplishes the same result, but requires more time. Additions should be dry to avoid hydrogen pickup. The result of these additions is a noticeable thickening of the slag.

Deoxidation—The temperature is now increased and silicomanganese added. This partially cleans the steel and improves the slag, which now takes on a greenish color. Some shops practice silicon reduction from the silicate slag instead of making a silicomanganese addition. The value of this practice is somewhat controversial, but is worthy of mention since good results are reported without the use of a deoxidizer at this stage. In this connection, one of the liveliest questions is so-called "over reduction," a condition resulting from high sulphur and low oxygen content. Over reduced steel is objectionable on account of low ductility in the final casting, and can apparently be prevented by melting down with a positive boil as already described, and then avoiding the too liberal use of deoxidizers.

After the slag has been properly conditioned final additions of ferromanganese and ferrosilicon are made both for the purpose of completing deoxidation and of obtaining the desired final analysis.

Tapping the Heat—After adjusting the temperature, the heat is tapped into the ladle, preferably of the bottom pour type. The slag may or may not be held back by means of a skimmer on the furnace. Comparative tests show no difference in physical properties between the two practices. When the slag is to be held back this can easily be done by plugging the tap hole, tilting the furnace until the slag line is above the level of the hole, then removing the plug. Any aluminum addition to take care of porosity due to mold gases or impurities should be added either on the bottom of the ladle before tapping, or else placed on the end of a rod and quickly pushed through the slag to the bottom of the ladle after the tapping is complete.

There has been much discussion on the subject of aluminum in castings, and various amounts are used in different foundries. The aluminum addition seems to be governed partly by the type of molding practice; green sand practice requiring heavier additions. Many foundries who ore down their charges to low silicon, carbon and manganese contents and then deoxidize with regular deoxidizers, get good properties and sound castings in dry sand molds with the addition of 0 to 4 oz. of aluminum per ton of metal. However, in green sand practice it has been found necessary in some cases to add 2-4 lb. per ton to get good properties and solidity. It might be added that the aluminum practice just described, combined with a calcium silicide addition in the ladle has been giving reliable results for many years.

Ladle Practice—Cleanliness about the ladle is always desirable. All remaining slag from the previous heat should be removed as thoroughly as possible. A smooth lining of gannister gives good results. In lip pouring the lining material sometimes slags with the steel, as can be seen if the stream is observed from the under side. To keep back the covering slag a skimmer brick is valuable. The use of bottom pour ladles in some cases results in cleaner steel. In making small castings the metal may be transferred to bull ladles or hand shanks as desired.

Much steel is tapped at about 3100°F. into the ladle. It is good practice to hold the metal for 5 min. or more in the ladle to allow entrained slag to float out. Some pressure castings are poured at about 2850°F. or less to improve solidity. Wrinkles are likely to occur at this temperature, however, impairing the appearance of the casting. Many thin section castings are poured at 2950-3025°. Temperatures of pouring at 3000°F. or above cause a breakdown of the mold in some cases resulting in burned-in sand, and consequently rough castings.

Steel Melting in the Coreless Induction Furnace*

By Dudley Willcox and G. V. Luerssen

History—The coreless induction furnace, often referred to as the high frequency furnace, first appeared in 1917. Up to about 1922 it was used only for laboratory melting and for precious and semiprecious metals. Its larger commercial possibilities have been steadily developed since that time.

In 1925 appeared the first large installation, which was used for tonnage melting of nickel-silver and other copper alloys. Twelve hundred kw. of 480 cycle power were used to energize twelve 650 lb. furnaces, and in 1928, 26,000,000 lb. of nonferrous metals were melted with this one installation.

In 1928, the first production steel melting furnace of this type was installed, utilizing 150 kw. of 2,000 cycle power derived from a standard or salient pole type generator. Since that time the use of these furnaces has increased rapidly. Most of the furnaces have been installed by the steel industry for melting tool steel and the various stainless steel alloys. The installations have been powered with 500, 960 or 1000 cycle single phase generators in units of 60-1700 kw. capacity. Furnace sizes range from 100-16,000 lb. and are quite in contrast to the largest steel melting induction furnace built up to 1922, which held 20 lb. Since that time the use of high frequency power has been extended to several hardening applications, such as surface heating of steel shafts, and for the hardening of crankshaft bearing surfaces. Rapid localized heating of either surface or linear sections of shafts and other steel parts is a most important later development of inductive heating. In 1937 two installations were made for heating pipe for forging.

Application—The high frequency induction furnace is being used both in the making of ingots and in the steel foundry. In ingot practice it is best adapted to the melting of stainless steel and special tool steels, particularly high speed. On account of the absence of carbon pickup, and low melting loss, it provides a good tool for the production of low carbon stainless steel, since it makes possible the use of a high percentage of stainless steel scrap in the charge. In the foundry it is valuable on account of its flexibility in operation, particularly in the production of small alloy castings.

Construction of the Furnace—The coreless induction furnace is essentially an air transformer in which the primary is a coil of water cooled copper tubing and the secondary the mass of metal to be heated. The essential parts of the furnace are shown in Fig. 1. The outer shell S is made of asbestos lumber and carries the trunnions T on which the furnace pivots in tapping or pouring. Most of the shell has been cut away to show the section of the furnace. The coil C, consisting in a helix of water cooled copper tubing, is lined with a layer L of refractory material and forms a protective coating against metal leaks. This layer is continued above and below the coil against the asbestos support R, and the firebrick top and base F. The coil lining and the firebrick bottom provide a cavity into which the refractory lining of the furnace is built. This lining may take the form of a thin wall crucible or supporting shell M packed into the cavity with grain refractory G, or it may be in the form of a sintered lining described later. This lining holds the charge or bath of metal B, and is grooved out at the top on one side to form the pouring spout D.

Due to the peculiarities in construction of the furnace, in which the primary coil is fairly close to the metal bath, the selection of suitable refractories is an important consideration. The first commercial steel melting furnaces were lined with thin walled silica sleeves surrounded with silica sand or powder. Silica linings are now in use both here and in Europe and are giving excellent results. Lining life of well over 100 heats is reported, the average being about 75 heats. The general practice is to use dry ganister lined with an asbestos or steel shell which melts down with the first heat and frits the inner wall of the sand.

Many American users prefer basic linings. Magnesia grain is often used with an inner shell or thin crucible of clay-bonded magnesia. The steel shell method may be used with any lining material, but it has been found less expensive and

*Prepared for the Subcommittee on Melting by Dudley Willcox, Ajax Electrothermic Corp., Trenton, N. J., and G. V. Luerssen, Carpenter Steel Co., Reading, Pa.

The personnel of the Subcommittee on Melting was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Herty, Jr., O. K. Farmiter, and Dr. G. B. Waterhouse.

more convenient in this country to use an inner shell of asbestos board made of Portland cement and asbestos fiber. This slags off on the first heat and bonds the inner layer of magnesia grain. Materials other than silica and magnesia which have been used are chromium ore, zirconium silicate, magnesite and various mixtures of magnesia and alumina.

Lining life varies greatly with the class of service. High chromium alloys tend to build up the inner wall so that it is necessary to scrape off the lining after each heat. Even then the capacity of the hearth tends to be reduced unless an occasional heat is made of some alloy such as silicon steel which cuts the lining or unless a suitable slag is used to prevent this building up. With a basic lining, and heats of stainless steel, a lining life of over 500 heats has been reported. When melting high speed steel, 100-200 heats may be expected.

Principle of Operation—In the operation of the furnace a high frequency current is passed through the primary coil or helix C (Fig. 1), inducing a much heavier secondary current in the charge, thus heating it by resistance to the desired temperature. The charge may consist either of a single lump of metal or a quantity of loose pieces such as ordinary steel scrap. Even comparatively fine turnings can be melted successfully if a moderate amount of heavier scrap is used. The current in the charge circulates in a path about its periphery in a direction parallel and opposite to that of the current in the coil. The higher the resistivity of the charge and the lower the frequency of the current applied, the greater is the radial thickness of the current path. While high frequency heating is effective over a wide range, it is practical to use about 1,000 cycles.

The heat is developed in the outer part of the charge and is quickly carried to the center by conduction, which is of course rapid through solid metals. After the charge starts to melt and a pool is formed in the bottom of the furnace a stirring effect occurs. This not only carries heat to the center of the charge by convection but accelerates melting by washing molten metal against solid metal. It also mixes thoroughly the elements in the charge, thus assuring uniformity. The flow lines in the molten bath are indicated in Fig. 2, showing that there are no "dead spots" but that every part of the bath is moved. The vigor of the stirring can be controlled by varying the power input. This is accomplished when only one furnace is attached to a high frequency generator by turning a rheostat controlling the generator voltage.

Melting Procedure—Rapid progress has been made during the past ten years in the application of this furnace to steel melting practice. The fact that development has come so fast, both from the standpoint of increase in furnace capacity and improvements in melting practice, makes it practically impossible to describe any generally used procedure at the present time. It is safe to say that in most plants using induction furnaces, the melting procedure is essentially a crucible process. Since the heat is generated entirely in the charge itself, melting is rapid and there is only a slight loss of the oxidizable elements. Furthermore, on account of rapidity of operation, preliminary bath analyses are not as a rule made. Consequently the charge is usually made up of carefully selected scrap and alloys of such aggregate composition as to produce the analysis desired in the finished steel without further additions, except possibly small amounts of ferromanganese, ferro-silicon, or other final deoxidizers.

The heavy scrap is charged first, and as much of the charge as possible is packed into the crucible. The current is turned on, and as soon as a pool of molten metal has formed in the bottom, the charge sinks and additional scrap is then introduced progressively until the entire charge has been added. Speed of melting depends upon the power input per pound of steel melted. With an input of 300 kw. it is possible to melt down a 1,000 lb. charge in 45 min.-1 hr., depending upon the character of the scrap. The additional time required to finish the heat depends upon the amount of time consumed in superheating and refining. Usually the total time is 1 hr.-1 hr. and 15 min.

In many cases no attempt is made in induction furnaces to melt under a slag cover, since, because of the convexity of the bath resulting from the stirring action, it is difficult to keep a slag blanket on the metal. Fortunately oxidation from the atmosphere is so slight that a slag does not appear necessary for protection alone. However, slags are being successfully used both during the melting down operation and for refining. The degree of convexity of the bath is governed largely by the rate of power input to the melt. A slag blanket on a one ton furnace powered with

300 kw. will be easier to maintain than on a one-half ton furnace with the same power input. The character and effectiveness of such slags is, of course, governed by whether the furnace is acid lined or basic lined. On basic lined furnaces it is reported possible to refine under a white slag similar in character to that used in arc furnace melting.

Fig. 1—Cross section drawing of induction furnace.

Fig. 2—Section of induction furnace showing stirring of the melt.

As soon as the charge is melted clear, and refining is completed, any further necessary additions of alloys or deoxidizers are made and the bath is superheated to the proper pouring temperature. The current is then turned off and the furnace tilted to pour the metal over the lip into the mold direct, into a funnel or pouring box placed over the mold, or into a ladle from which it is later poured into molds. In foundries making small castings it is sometimes the practice to pour into shank ladles. As soon as the heat has been poured, the furnace is scraped clean of adhering slag and immediately recharged for the next heat.

A variation of the usual melting procedure adapted to the melting of certain special alloys, consists in what is known as vacuum melting. In this process a hood is placed over the furnace and exhausted, so that melting is conducted in the absence of air or other gases.

Crucible Process for Steel Making*

By Owen K. Parmiter

History—The production of iron and steel by a crude form of the crucible process was practiced thousands of years before the dawn of the present commercial era. The hardening properties of these ancient steels were the result of the carburizing action of the fuel, which was usually charcoal. The importance of this "carburizing" or "cementing" action was not clearly understood at first, but later it was applied to good advantage in the development of "blister steel," "shear steel" and "double shear steel." All of these steels were carburized at temperatures considerably under the melting point of the iron.

Huntsman in 1740 revolutionized the original process by melting broken pieces of the carburized blister steel in a crucible, thereby obtaining a more uniform steel. The first tool steel company was established in 1751. Mushet, early in the last century, substituted refined iron for the blister steel scrap in his crucible mix. Charcoal was added to serve as a carburizer, and the mixture was melted to form "cast steel," as it later became known. From that time on, progress in the manufacture of tool steel was relatively slow until the advent of modern analytical chemistry afforded further impetus to the production of quality steel.

Description of the Furnace and Process—The modern crucible melting furnace is of the Siemens regenerative type or some modification of it. The usual furnace has a capacity of 30 pots, each pot accommodating a little less than 100 lbs. of steel. The furnace has 5 separate melting compartments, each with an opening or "hole" which allows the operator to examine the pots during the melting process without an excessive loss of heat from the furnace. A transverse section of a crucible furnace is shown in Fig. 1 in which (A) is the melting compartment or hole. Each compartment holds 6 pots (B), and is covered with 3 brick lined covers (C), which can be pushed aside when examining the pots, or removed at the time of "pulling" or "drawing."

Regenerative gas and air chambers, (D) and (E), are arranged on either side of the melting holes. The fuel, which may be either natural or producer gas, usually the latter, is fed into the gas chambers under valve control. The necessary air for combustion is furnished by controlled stack draft. The flame resulting from the combustion of gases in the air and gas chambers is led through ports (F), three on each side of the melting compartment. Gas and air are reversed from one side of the furnace to the other every 20 min.

The bottom of the furnace proper is formed by cast iron bed plates (G). These are supported on the sides by the foundation wall of the gas chamber, and are protected from the heat by heavy tile brick (H). Over these brick, coke dust (I) is scattered to a depth of about 12 in. This

Fig. 1—Crucible furnace.

coke serves as a cushion or bed for the pots, and is of assistance in maintaining an even temperature.

The average number of heats from a crucible furnace is 6 every 24 hr., or 33 heats per week. The average recovery of steel ingots from a 30-pot furnace is about 2800 lb. per heat. The pots are made from a mixture of natural flake graphite, ball clay and silica sand, which is thoroughly wet-ground, and spun to shape. In use the pots are covered with a cap of the same material.

*Prepared for the Subcommittee on Melting by Owen K. Parmiter, Metallurgical Engineer, Frith Sterling Steel Co., McKeesport, Pa.

The personnel of the Subcommittee on Melting was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Harty, Jr., Owen K. Parmiter, and Dr. G. B. Waterhouse.

Approximately 3 hr. are required to melt a crucible charge of ordinary carbon steel. To determine when the raw materials in each pot are melted, the melter uses the "looking stick," which is a steel rod about $\frac{3}{4}$ of an in. in diameter and 6-7 ft. long. This operation is performed as rapidly as possible and the cover replaced immediately after each test. After the raw materials have melted, the charge is held for a period of "dead melting" which is about 1 hr. When the proper temperature is reached, the pots are lifted out or "pulled" by hand tongs and passed to the "teemer," who pours their contents into an ingot mold or a ladle.

While this description covers the modern furnace and melting practice used almost universally in America, a large part of the crucible steel made in Europe is still made by the original Huntsman process in coke fired furnaces.

Coke Fired Furnace—The coke fired furnace is in reality a squat shaft furnace, lined with ganister. The body of the furnace is closed by fire bars at the bottom, and has a fire brick cover at the top. Near the top of the furnace is a side flue leading to a chimney. The furnace accommodates 2 crucibles, each capable of holding about 75 lb. of steel. The crucibles or pots may be either clay or graphite, and in England the clay pot is still generally used. These pots are placed on fire brick stands resting on the fire bars and the charge introduced into the crucibles through sheet iron funnels. Lids are placed on the pots, and the whole of the inside of the furnace, still hot from the previous heat, is filled with coke.

The cover is placed in position, the dampers adjusted and the material allowed to melt, an operation which takes from $3\frac{1}{2}$ -4 hr. for the first heat and $3\frac{3}{4}$ hr. for subsequent melts. Generally, the operation of coke melting is carried out in precisely the same manner as the operation of gas melting and the success or failure of the operation depends very largely upon the skill of the operator.

Selection and Preparation of Raw Materials—The crucible method cannot remove such impurities as sulphur and phosphorus. In selecting raw materials, this fact must be given careful consideration. The base of many of the crucible mixes is puddled or charcoal iron, which must be of the best composition obtainable. The steel scrap should be clean and as nearly as possible of uniform size. The charcoal should be of the hardwood variety, in pea size pieces, with a high fixed carbon content. The ferromanganese should be of the low carbon variety, in clean, uniformly small lumps. The average crucible mix will consist approximately of the following:

Typical Crucible Furnace Mix

Carbon Steel (1.00%C.)

Ingredients	Actual Amounts, lb.	% by Weight
Puddled bar iron.....	76	80.50
Crucible steel scrap.....	17	18.00
Charcoal (75% fixed C.).....	1.25	1.25
Ferromanganese (80% Mn).....	0.25	0.25
	94.5	100.00

8 oz. of river sand per pot are sometimes used to form flux. Some use clay, black oxide of manganese, or crushed acid slag. All of these materials are accurately weighed and checked separately for each individual pot. The types of charge often vary widely with different manufacturers, some using higher percentages of tool scrap, some using foreign wrought irons, and others domestic irons.

In addition to the use of charcoal as a carburizer, wash metal, a purified iron containing 3.75% carbon, has been extensively used. As a substitute for wash metal, the Swedish white charcoal iron has had some application.

Method of Charging—The charcoal, sand, and ferromanganese are charged on the bottom of the pot, followed by all of the iron. The scrap having the lowest melting point is added near the top of the pot. Mechanical shaking devices are used to thoroughly pack the charge so that the covers will fit tightly on the crucibles.

As soon as the pots are emptied of their contents of finished steel, they are refilled with a new, cold charge, and again set in the furnace. The pots are brought up to the melting hole on small specially designed buggies. Usually a pot can be refilled 5 times, thus making the total life of the pot about 6 heats.

Melt Down and "Dead Melting" Process—The melt down should be accomplished rather quickly in a hot furnace, so that steel is melted and clear in from 2½-3 hr. After this, about 1 hr. is spent in "killing" or "dead melting." During this important operation, the furnace should be run considerably on the hot side of the proper range for the first 30 min., tapering off to the cool side for the remainder of the "firing" period. This operation serves to deoxidize and degasify the molten metal, at the same time permitting any inclusions of nonmetallic particles to come to the top and be absorbed by the slag. During this "soaking" period, the molten steel absorbs both carbon and silicon from the pot. The carbon pickup will vary from 0.05-0.15%, depending upon temperature and age of pot. When carbon pickup is undesirable, a graphite crucible with approximately ¼ in. of clay lining may be used. New graphite crucibles kill the steel more quickly than older ones because the metal absorbs more carbon and silicon from a new pot. As the pot gets older it is good practice to add more carbon and a small amount of ferrosilicon to the charge. By training and experience, the melter determines when the steel has had sufficient "fire" to rid it of nonmetallic particles and dissolved gases. Insufficient "fire" is indicated by a prolonged burst of sparks upon removal of the crucible cap. Too much "fire" produces an ingot with a "leady" structure and the resulting bar fracture appears "dry" and "dull."

Slags and Refining—The term "refining" as applied to the melting of ordinary steel usually implies the removal of undesirable impurities such as sulphur and phosphorus by oxidation or reduction in the presence of a basic flux. In crucible melting, such a process of refining is not possible because, while the pot is reducing in action, it is also of a siliceous or acid nature, which necessitates the use of an acid slag of glass or sand. Oxides and dissolved gases are removed by the reducing action of the pot. Silicon is absorbed in amounts as required and under ideal conditions to insure complete deoxidation. Carbon in the proper form is absorbed slowly from the charcoal or wash metal by the iron to produce carbides.

Composition and Temperature Adjustments—In crucible melting, all ingredients are generally added to the original charge (manganese and silicon are sometimes added to the ladle). Once the pot cover becomes sealed by the fluxing action of the container, it is seldom removed until the steel is ready to "teem" or pour. Once a mix is proven, adjustments are seldom necessary. Occasionally the carbon content may vary slightly from the desired amount, but this can be corrected by adjusting the amount of charcoal in the mix for the following heat. The "carbon throw" from the pot varies, depending upon the number of heats that have been made in the pot, but this can be regulated by proportionately increasing the amount of charcoal in the later heats. Time and temperature during the killing period directly affect the carbon "pickup," which will vary considerably unless operating conditions are held uniform by the melter.

The proper temperature for teeming depends largely upon the skill and experience of the melter. The temperature, which may be adjusted for either "hand teemed" ingots or for "ladle practice," is always higher for the ladle work. In hand teemed work, the speed of pouring can be regulated to compensate for variations in temperature.

Deoxidizers—For deoxidation, crucible steel depends upon a silicon content absorbed from the pot. If the killing time has been sufficient to give the steel the proper silicon content, and if the temperature is correct, the steel is ready for pouring. Just before this teeming operation, the slag is removed from the molten steel, thus exposing its surface to the atmosphere. Provision for this temporary exposure to oxidizing influences is made by dropping a "pill" of pure metallic aluminum into the pot. Aluminum not only prevents oxidation and keeps the steel "quiet" until it can be teemed, but it also degasifies the metal.

During recent years, the crucible furnace has been largely supplanted by the electric furnace for the melting of tool steel. The crucible process has not been abandoned entirely, however, since it still affords a method by which steel can be made efficiently in small quantities.

Metals and Ferroalloys Used in the Manufacture of Steel

By W. J. Priestley*

Introduction—Howe has aptly defined ferroalloy as "iron so rich in some element other than carbon that it is used as a vehicle for introducing that element in the manufacture of iron or steel".

A number of ferroalloys are in common use. Some of them are used for the peculiar properties they impart to steel when in solid solution with the iron or when they combine, either wholly or in part, to form a carbide; others are used for the beneficial effect they have on impurities in the steel; and still others are employed to counteract harmful oxides or gases and they may not remain in the steel after solidification, but act as fluxes or scavengers of objectionable impurities.

Standard Ferromanganese—Manganese is most generally introduced to the molten steel in the form of ferromanganese. The standard grade of ferromanganese has approximately the following analysis:

Manganese	78-82%
Iron	15-19%
Carbon	6-8%
Silicon, max.....	1.00%
Phosphorus, max.....	0.35%
Sulphur, max.....	0.05%

It is furnished in lumps up to 75 lb. each, and when made under the best conditions will not disintegrate or crumble. It is used in all grades of steel including Bessemer, open hearth, and electric for forgings, rolled products, and castings. Manganese combines readily with sulphur, forming manganese sulphide which is less harmful in steel than iron sulphide. Manganese is a fairly strong deoxidizer, and its oxide forms a fusible slag with other oxides, such as silicates, and has a beneficial scavenging effect. In effervescing steel it is desirable to keep the manganese between 0.30-0.40%, while in deoxidized steel for forgings or castings it ranges from 0.40-0.90%. Special alloy steels are made with a manganese content from 1-2% and from 12-14%. In commercial steel practice, ferromanganese is sometimes added to the ladle, resulting in a loss of from 10-20% manganese. When better steel is required, freer from slag and nonmetallic inclusions, the ferromanganese is added to the furnace. The manganese loss in this case is from 10-40%, depending upon the degree of deoxidation previously done on the bath in the furnace. Ferromanganese is often used in the furnace to increase residual manganese while the carbon is being adjusted. The melting point of the 80% ferromanganese is between 2280 and 2325°F.† Manganese improves the rolling and forging properties of steel.

Low Carbon Ferromanganese—Where manganese is desired in a low carbon steel and standard ferromanganese cannot be used on account of its high carbon content, low carbon ferromanganese is substituted. This contains 80-85% manganese, max. 1% silicon, and may be obtained with either max. 0.10 or max. 0.50% carbon. This ferroalloy is supplied in lumps up to 10 lb. each and may be added to the ladle or furnace. The latter is preferable when loss from oxidation is not too great.

Medium Carbon Ferromanganese—This alloy is used for making steel with a slightly higher carbon content than obtained from the use of low carbon ferromanganese. It is generally used for making low carbon manganese steel containing between 1.50 and 2.00% manganese. It is sometimes used in the manufacture of 13.00% manganese steel when large quantities of returned scrap with high silicon content are in the charge.

The ferroalloy is furnished in different grades depending upon the carbon and silicon analysis of the steel. Three principal grades are as follows:

	(1)	(2)	(3)
Manganese	80-85	80-85	80-85%
Carbon	1.50 max.	1.50	0.75
Silicon	1.50 max.	2.50	7.00

*Vice-President, Electro Metallurgical Co., New York.

†The melting temperatures given were obtained from data published by the Bureau of Mines.

It is supplied in lumps up to 75 lb. for furnace additions and in crushed form, 2½ in. dia. or smaller, for ladle additions.

Spiegeleisen or Spiegel—Spiegeleisen or spiegel is virtually a high manganese pig iron used in Bessemer and basic open hearth practice. It usually falls within the following chemical range:

Manganese	15-30%
Carbon	4.5-5%
Silicon, max.	1.00%
Sulphur	0.06%
Phosphorus	0.15%

The melting point of spiegeleisen is between 1950 and 2265°F. In Bessemer practice molten spiegel from a cupola is added to the steel, after the blow, for recarburizing and obtaining the desired manganese content. In the case of low carbon Bessemer steel, 80% ferromanganese is used in place of spiegel. Spiegel is frequently used with scrap and pig iron in an open hearth charge in order to raise the manganese content. It is more economical, however, to use a high manganese pig iron containing from 1.50-2.50% manganese.

In making effervescing steel, manganese is a good scavenger on account of its deoxidizing properties and its beneficial effect upon steel in the elimination of sulphur. Some of the troubles generally encountered in open steel are overcome by adding 0.10-0.20% manganese in the form of ferromanganese or by adding spiegel after oreing the bath. In the manufacture of deoxidized steels of forging quality, either carbon or alloy grade, or high grade castings, an addition of manganese in the form of ferromanganese or spiegel has been found highly satisfactory to clean up the bath after oreing. This is frequently accompanied by the addition of silicon in the form of silico spiegel or silicomanganese. Silico spiegel when made in the blast furnace contains approximately 4% silicon and 20% manganese. The electric furnace product contains approximately 8% silicon and 28% manganese.

Silicomanganese—For making low carbon steel in which silicon is not objectionable, silicomanganese may be used effectively for the introduction of manganese on account of its low carbon content. The use of this alloy in the refining stages of steel melting leads to the production of denser steel with fewer oxide inclusions. It is also used effectively for 13% manganese steel when large quantities of returned scrap are in the charge. Makers of low carbon-chromium and manganese steels favor it on account of the low ratio of carbon to manganese. Four different grades are available containing approximately the following percentages:

	(1)	(2)	(3)	(4)
Manganese	65-70	65-70	65-70	65-70%
Silicon	20-25	16-20	14-18	12-14%
Carbon	Max. 1.00	Max. 2.00	Max. 2.5	Max. 3%

This is furnished in lumps up to 75 lb. each or in crushed form.

Ferrosilicon Alloys—Ferrosilicon is supplied in a number of grades depending upon its purpose. Silicon has a great solvent power for gases and a stronger affinity for oxygen than manganese. It is, therefore, used for its quieting effect upon wild or oxidized steel. It may be used in effervescing steel in small amounts to clean up the bath. Larger percentages of silicon are used in deoxidized steel for high grade forgings, rolled products, and castings. The range of silicon content in the various grades of steel is approximately as follows: Effervescing steel, sheets and boiler tubes, below 0.02; semikilled steel, under 0.10; forging quality steel, 0.10-0.25; steel castings, 0.30-0.80; sheet steel for magnetic circuits in alternating fields, 1.0-5.0%.

15% Ferrosilicon—As a deoxidizer and scavenger for furnace use, silicon may be procured in a ferroalloy analyzing: Silicon, 14-16; carbon, max. 1; phosphorus, max. 0.05%. This is furnished in pigs up to 100 lb. each. The melting point of 15% ferrosilicon is about 2180°F. When used as a furnace deoxidizer, a large portion of the silicon added is not recovered but rises out of the metal as a silicate. In forging steels or alloy steels, it is useful as a preliminary scavenger for maintaining uniform analysis and higher recovery of alloying elements such as manganese and chromium when added later.

50% Ferrosilicon—The largest tonnage of silicon is consumed in the form of 50% ferrosilicon containing approximately 47-52% silicon and 48% iron. Its melting point is about 2170°F. This alloy is furnished in lumps up to 50 lb., and when made

under the best manufacturing conditions will not disintegrate or crumble when exposed to the air. In acid open hearth and acid electric furnace practice this alloy may be added to the ladle or to the furnace. The silicon loss in each instance is approximately 5%. In basic open hearth practice best results are obtained by adding it to the ladle in crushed form. The silicon loss varies from 10-30%, depending upon the degree of previous deoxidation of the bath and the amount added.

75% Ferrosilicon—For making steel of higher silicon content, some melters prefer a 75% ferrosilicon alloy. The approximate analysis is: Silicon, 75-79; iron, 20%. This is furnished in lumps up to 50 lb. each or in crushed form. The melting point is about 2150°F. The addition of concentrated grades of ferrosilicon to molten steel generates heat that is particularly apparent in the production of steels with more than 2% silicon and steps should be taken to allow for this change.

90% Ferrosilicon—In cases where ladle additions of cold ferroalloys must be large in order to give a high silicon content in the steel, it is desirable to use 90% ferrosilicon. This alloy contains approximately: Silicon, 90-94; iron, 4.50%. This is furnished in lumps up to 35 lb. each or in crushed form. The melting point is about 2150°F.

Ferrochromium—The amount of chromium added to steel for structural purposes varies from 0.50-6.00%. When chromium is added in amounts between 11.00-14.00% with the carbon above 0.20%, the steel resists corrosion after being heat treated. However, if the carbon is below 0.10% and the chromium 13.00% or higher, the steel resists corrosion and oxidation in both the heat treated and untreated conditions. For resistance to more severe corrosion and oxidation at higher temperatures, chromium is added in amounts up to 30%.

For steel containing medium carbon and chromium, a high carbon ferrochromium of approximately the following analysis is used:

Chromium	60-72%
Carbon	4- 8%
Silicon	2- 3%

This alloy is furnished in lumps up to 75 lb. or in crushed form. On account of its slow melting to a liquid state, ferrochromium should be added to the furnace in all cases and never to the ladle. Its melting point has been reported from 2200-2370°F. In the basic electric, acid electric, and acid open hearth processes, the chromium loss is approximately 5%. With the basic open hearth process approximately 10% chromium is lost.

Low Carbon Ferrochromium—For making low carbon steel, where high carbon ferrochromium would be unsuitable, a low carbon ferrochromium is used. This is supplied in a number of different carbon grades to meet the steel maker's special requirements.

These grades range from a maximum of 0.06 to a maximum of 2.00% carbon, chromium 60-72%, and with a maximum of 1.00% silicon. The melting point ranges from 2300-2480°F. This alloy is furnished in lumps up to 75 lb. or in crushed form.

High Nitrogen Ferrochromium—High nitrogen ferrochromium is available in both the high carbon and low carbon grades. The chromium content of these high nitrogen ferrochromiums varies from approximately 60-72% and the nitrogen content from 0.60-0.70%.

Ferromolybdenum—In engineering steels the amount of molybdenum rarely exceeds 1% and is nearly always used in combination with nickel, chromium, vanadium, or manganese. In most cases the amount is between 0.15 and 0.50%. In the molybdenum high speed steels, the molybdenum may be as high as 10%, replacing part of the tungsten.

Ferromolybdenum has approximately the following analysis:

Molybdenum	55-65%
Sulphur	max. 0.25%
Silicon	max. 1.50%

Ferromolybdenum is furnished in two grades containing maximum 0.50 and maximum 2.00% carbon. It is generally used in crushed form, 1 in. and down. Ferromolybdenum is not ordinarily added to steel in the ladle, but is usually added in the furnace. Since it does not oxidize under steel making conditions, it may be charged into the furnace any time up to one half hour before tapping. Molybdenum steel scrap should be kept separate from other steel scrap on account of its valuable

molybdenum content which may be recovered in remelting. The recovery of molybdenum is in excess of 90%. The approximate melting point is 2965°F.

Calcium Molybdate—Calcium molybdate contains about 40% molybdenum, 25% calcium oxide, and no carbon. This product is suitable for steel made in the open hearth and electric furnace. The molybdenum recovery in this form is equal to that obtained from ferromolybdenum.

Calcium molybdate is not made as a final addition like most ferroalloys, but is added either with the charge or at any time during the progress of the heat, preferably after the heat is melted. In a basic electric furnace it may be added immediately after slagging off with good results.

Calcium-Molybdenum-Silicate—Calcium-molybdenum-silicate contains about 40% molybdenum, 23% calcium, and 16% silica. As this product is practically neutral in its action, it is suitable for additions to either acid or basic furnaces.

Due to its heavy, lumpy consistency, it can be added at any time during the heat from the melt down up to within a few minutes of the tapping. When thus added it gives a uniformly high recovery and uniform distribution.

Ferrovandium—The amount of vanadium added to engineering steels is generally 0.10-0.25%. In high speed steel, the proportion ranges between 1 and 5%. Alloy tool steels other than high speed contain from 0.20-1.00%. It is added to steel in the form of ferrovandium, the approximate analysis of which is as follows:

Vanadium	35-40%
Silicon	1.50-8%
Carbon	0.20-3%

It may be obtained in lumps up to 10 lb. or in crushed form. Vanadium oxidizes readily so in open hearth practice it is usually added to the ladle. Its melting point is between 2600 and 2700°F. The vanadium loss in this process is approximately 10%. In basic electric practice, it is generally added to the furnace with a vanadium loss of approximately 4%.

Titanium—Several forms of titanium alloys are used in steel making. The high carbon grade is known as ferro carbon-titanium and contains about 17% titanium, 7.50% carbon, 2.50% silicon and 1.00% aluminum. It is used as a deoxidizer and scavenger, leaving only barely appreciable amounts of titanium in the solid steel. In low carbon effervescing sheet steel, ferro carbon-titanium is used to prevent blisters and other surface imperfections. In medium or high carbon killed steels ferro carbon-titanium is used for deoxidation and to promote freedom from segregation. Titanium reacts with nitrogen in the steel and forms minute pink crystals of titanium nitride. Several low carbon grades in use are known as low carbon ferrotitanium. One grade is made by the aluminothermic process and contains about 25% titanium, 6.00% aluminum; another grade is made in the electric furnace and contains 15-20% each of titanium and silicon with less than 1.00% aluminum and less than 0.50% carbon. In these forms the titanium acts as a deoxidizer and scavenger and also as an alloying element. For austenitic stainless steels some prefer a grade containing 20-25% titanium while others find an alloy with 40-45% titanium satisfactory. In both grades it is desirable to keep the silicon and aluminum as low as possible and the carbon is usually specified under 0.10%.

Ferrotungsten—The principal use of tungsten is the manufacture of high speed steels which contain a wide range of tungsten, from 14-20%. It is also the principal constituent of permanent magnet steel, and hack saw steel, generally containing from 1-5% tungsten. Tungsten steel is made either in the crucible or electric furnace.

Ferrotungsten has approximately the following analysis:

Tungsten	78-83%
Silicon, max.	0.75%
Carbon, max.	1.00%

Ferrotungsten has a melting point between 3275 and 3450°F. and should, therefore, always be added to the furnace or crucible. The size commonly used is 1 in. and down. On account of its melting point being lower than tungsten powder, some steel makers prefer ferrotungsten.

Nickel—Nickel is used in engineering steels from 2-5% and in higher percentages for heat resisting and acid resisting parts. Nickel is added to the furnace in a metallic form containing about 99% pure nickel. It is not removed from steel by

oxidation at steel making temperatures, therefore, nickel scrap should be kept separate from other steel scrap on account of its recovery value. As there is no furnace loss, the nickel may be charged into the furnace any time during the progress of the heat.

For steel making the following two grades of nickel are available:

	Electrolytic Cathode Nickel, %	Remelted Electrolytic Nickel, %
Nickel (plus cobalt).....	99.95	99.60
Melt point, °F.....	2650	2600

Ferrocolumbium—Columbium has a strong affinity for carbon and forms a stable columbium carbide constituent. It is used for modifying the air hardening characteristics in plain chromium steels of the corrosion resisting grades. Since columbium inhibits intergranular corrosion in austenitic 18-8 stainless steel, it is used in this grade of steel requiring welding or long time holding up to 1500°F. Columbium also increases oxidation resistance in chromium steels at elevated temperatures.

The amount of columbium added to steel varies from five to ten times the carbon content depending upon the service in which the steel is used. It is available as a ferrocolumbium alloy containing 50-60% columbium. When added to the steel after deoxidation, and 12-15 min. before tapping, 80% of the alloy will be recovered.

Zirconium—Zirconium is used as a deoxidizer and scavenger of steel in amounts between 0.05 and 0.10%. It acts on the oxygen and nitrogen in the steel, tending to eliminate them as well as nonmetallic inclusions. An addition of 0.08-0.10% will usually result in a fine grain steel. In amounts of 0.10-0.15%, it forms zirconium nitride. When present in steel above 0.15%, it combines with sulphur, forming zirconium sulphide. This prevents tearing in rolling and produces a better surface on high sulphur steel. For steel of high silicon content, the 12-15% zirconium alloy is used, the approximate analysis of which is as follows:

Zirconium	12-15%
Silicon	39-43%
Iron	40-55%

For steel of low silicon content, the 35-40% zirconium alloy of the following analysis is used:

Zirconium	35-40%
Silicon	47-52%
Iron	6-10%

Zirconium is frequently added to steel in the form of a ternary alloy containing 20-24% zirconium, 10-12% manganese, and 58-62% silicon. It may be most effectively added to steel in the ladle, where it has a strong deoxidizing action and forms a fusible slag which tends to rise out of the metal. For the control of grain size, an alloy containing 45% silicon, 7% aluminum, 7% vanadium, and 7% zirconium is used as a ladle addition.

Cobalt—Cobalt resembles nickel in appearance and properties. It has been added successfully to high speed steel in amounts from 1-12% for the purpose of obtaining a cutting tool which would hold a sharp edge. It is used for making magnet steels containing about 35% cobalt. An alloy containing about 19.5% cobalt is used as a substitute for platinum for certain uses. It is also used for a new electrical resistance alloy for high temperatures. Pure cobalt has a melting point of 2631°F. It is usually added in the form of cobalt metal of about 97-98% pure, or in the form of ferrocobalt containing 90-94% cobalt, balance iron.

One of the chief uses of cobalt, in this country, is in the manufacture of Stellite. It is also often used as an alloy in making permanent magnet steel.

Aluminum—Because it is an extremely active deoxidizer and degasifier, aluminum is used in substantially all steel making processes. It is used as a mould addition to quiet wild metal. It is also used in the ladle for obtaining a fine grain size and to prevent pin holes in steel castings. Aluminum is a constituent of the majority of nitriding steels. Aluminum is available in several forms such as shot, sticks and small ingots. The amount used depends on the steel making practice and the use for which the steel is intended. The melting point of aluminum is approximately 1218°F.

Copper—When used alone as an alloying element, the range of copper is between 0.20 and 0.50%. The rust resisting properties of steel are claimed to be increased by raising the copper content to 0.40% along with 0.05% molybdenum.

Since copper does not oxidize in steel it cannot be removed from scrap once it is present as an alloy. This results in small percentages of this element remaining in all steel made from copper bearing scrap.

Copper has a low melting point (approximately 1981°F.) and alloys readily with steel up to about 1%. Additions are made to the furnace in the form of pure copper pigs. Copper is harmful to some grades of steel, particularly hardened tool steels containing over 0.60% carbon. The detrimental effect of copper is directly proportional to the carbon. Some improvement in the poor rolling properties of high copper steel may be obtained by increasing the manganese or by the addition of half as much nickel as copper.

Calcium-Silicon—Calcium is exceedingly active chemically and combines readily with oxygen and other gases and reduces nearly all metallic oxides on heating. Calcium-silicon is used as a deoxidizer, degasifier and reducing agent in steel making. Both calcium and silicon are active deoxidizers and form a low melting point slag which readily frees itself from the metal. Calcium-silicon also improves the fluidity of the steel. It is usually used in crushed form, 2 in. and down, and is added in the ladle in open hearth steel making as a final deoxidizer. From 2-6 lb. are used per ton of steel. In electric furnace melting it is used preferably in the furnace where it quickly forms a fluid reducing slag.

The range of elements in this alloy is as follows:

Calcium	28-35%
Silicon	60-65%
Iron	3- 6%

Its melting point is between 1850-2100 degrees F.

Calcium-Manganese-Silicon—This is a ternary deoxidizer containing three active elements, the combination of which forms a scavenger for oxides, gases and nonmetallic impurities in steel. When used as a final alloy addition to steel it produces a clean, coarse grained structure with deep hardening properties. It is also used to deoxidize stainless steel, high speed tool steel. The alloy contains 16-20% calcium, 14-18% manganese, 55-60% silicon. The alloy addition is generally based upon a silicon content required in the steel.

Its melting point is between 1800-2000°F.

Aluminum as a Deoxidizer

By John Chipman*

Aluminum is used in the manufacture of many widely different grades of steel. Aside from its rather limited use as an alloying element, its main purpose is to reduce the content of ferrous oxide in the liquid steel. When this reduction amounts to substantially complete elimination, the resultant steel is found to be fine grained, as judged by the McQuaid-Ehn test.

Of the elements commonly used as deoxidizers aluminum is the most potent, and affords the most nearly complete removal of dissolved ferrous oxide. The reaction in its simplest form is written as follows:

Fig. 1—Deoxidation diagram for aluminum in steel.

cleanliness. The amount used ranges from a few ounces to as much as four lb. per ton, depending upon the grade of steel, the slag, other deoxidizers used, and the grain size desired.

The completeness with which aluminum removes dissolved FeO from the steel bath is shown in Fig. 1, which was obtained from the calculated equilibrium constant of the reaction. Fig. 1 shows, for example, that in a bath at 2910°F., if enough aluminum is added to react with the other oxides present, and to leave a residual, 0.01% metallic aluminum dissolved in the steel, the content of dissolved FeO will be reduced to 0.002%. Similarly, if the bath temperature is 3090°F., and the residual metallic aluminum 0.02%, the dissolved FeO will be less than 0.005%. It should be emphasized that these figures are based upon calculated, rather than experimental, values of the equilibrium constant. In view of the limitations of present experimental methods when applied to small amounts of aluminum and oxygen at high temperatures, the calculations are probably more dependable than direct determinations.

Aluminum is added to rimming and semikilled steels to diminish the content of active FeO and to control the action in the molds. The amount used in rimming steels will range from 0 to 0.4 lb. per ton in the ladle (for semikilled 0-0.7), and up to half this amount in the molds. The amount will vary with the carbon and manganese content of the steel, the composition of the slag, the size of the heat, and the size of the mold. In general the rimming action contributes to the removal of the products of deoxidation and the use of aluminum in the molds does not necessarily lead to the presence of nonmetallic inclusions. The amount of aluminum added is never sufficient to react with more than a small fraction of the ferrous oxide present. Reference to the deoxidation diagram shows that in this case the residual metallic aluminum in the steel is practically nil.

When an excess of aluminum is employed, the inclusions formed in the reaction consist of Al_2O_3 , more or less contaminated by FeO and other oxides. When a deficiency of aluminum is used, the resultant inclusions are mainly ferrous aluminate, whose exact composition is unknown and probably variable.

In killed steel the aluminum is generally added to the ladle, although in certain grades of electric furnace steel some melters add it in the furnace. Its use in the molds in killed grades is usually prohibited by consideration of

The Use of Aluminum for the Control of Grain Size in Commercial Steels

By H. W. McQuaid*

The importance of the control of grain size in commercial steels has become so well recognized in recent years that the method used in obtaining this control is of general interest to everyone responsible for the treating and application of commercial steel. "Grain size" as used here refers to the austenite grain as indicated by the McQuaid-Ehn carburizing test or other suitable measure of austenitic grain size and is rated usually according to the chart of the A.S.T.M.¹ (See p. 750 and 754.) Practically every heat of carbon and alloy steel specified in this country for heat treated parts is made according to a certain melting practice designed to provide properties in the steel which will make it most suitable for the part in which it is to be used. The McQuaid-Ehn grain size is used as an indicator of the characteristics of the particular steel in its response to normalizing, heat treatment, and other processing, and has become in many cases of equal importance to the chemical specification in the results obtained in the commercial heat treatment of steels.

The most important single factor in the control of grain size is aluminum, so that this element which at one time was considered detrimental as an addition to quality steel, has become a familiar sight on the melting furnace floor. It has been found by experience that additions of aluminum from a few ounces up to as high as 4 lb. per ton result in variation in grain size and characteristic properties according to the condition of the steel to which it is added.

It might be well at this point to note that the making of steel to a definite grain size range is only commercially possible when the specifications cover either a coarse grained type or a fine grained type. Although it is possible, and specifications require it at times, that steel be made which will show according to the McQuaid-Ehn test an intermediate grain size range, it should be remembered that steel of this type requires very careful control of every factor and is not usually considered "commercial."

One of the first published evidences of the effect of aluminum on grain size is shown in Fig. 1. There is no doubt but what prior to this time aluminum was added to improve certain properties of steel, but it was not until a little more than 10

Fig. 1—Fine grain obtained by aluminum deoxidation as contrasted with the coarse grain of manganese deoxidation. (Left) Hypereutectoid specimen from ingot deoxidized with aluminum. (Right) Hypereutectoid specimen deoxidized with ferromanganese. $\times 200$.

years ago that active work was done in connecting the aluminum addition with grain size specifications. As soon as the first grain size chart appeared in 1924 and some steel users insisted on obtaining steel of a definite grain size, it was found

*Republic Steel Corp., Massillon, Ohio.
This article was not revised for this edition.

necessary to develop a melting technique which would make it possible to meet these specifications commercially (Fig. 1).

It was known that in the plain carbon grade particularly, that fine grained steel could be produced without the use of aluminum, depending entirely on the presence of excess FeO, but that when so produced the quality of the steel was decidedly inferior to that desired and recourse was had to aluminum. It was soon found that if the steel were to be produced to meet a given grain size specification by the use of aluminum, that it was necessary to give much greater thought to the deoxidation of the steel prior to the aluminum addition; and thus, a great deal of study was required of open hearth deoxidation with a view to more completely controlling the variables of oxidation.

Aluminum, being one of the most active deoxidizers of which we know, must be carefully added to a bath of liquid steel if the losses due to oxidation are to be within reasonable limits and also if the aluminum is to be effective in its role as a grain growth control agent.

It is of course evident because of the great affinity aluminum has for oxygen, that the addition of stick aluminum to the ladle will result in a high loss of aluminum in the form of oxidation at the surface of the steel. For this reason a special effort should be made to keep the aluminum as added as completely submerged as possible to prevent not only the high loss of aluminum in the slag but also the presence of large masses of aluminum oxide in the steel itself.

It has been found that to be effective, aluminum must be added in connection with silicon. At the present time we do not know why silicon plays such an important part in connection with aluminum, but it is known that in the absence of silicon, aluminum is much less effective. For this reason deoxidation with silicon is a necessary requirement of all heats in which aluminum is to be used to control grain size.

The three most important factors which govern the effectiveness of the aluminum addition in controlling grain size are the state of deoxidation of the bath, the temperature of the bath, and the time of the aluminum addition in relation to the solidification of the ingot. One of the difficult problems of determining the proper addition of aluminum to an open hearth heat to make fine grain steel was the control of the deoxidation and temperature prior to the addition of aluminum.

In the electric furnace, melting under a so-called carbide slag, the FeO in the slag and in the bath itself is relatively low so less aluminum is required than when steel is made under a basic open hearth slag.

In order to arrive at a satisfactory basis for the addition of aluminum to open hearth steel, the charge must be carefully regulated as well as the rate at which the oxidation of the carbon takes place, so that when the time comes for the final shaping up, we can arrive at a bath which is under control not only as far as carbon is concerned, but which has also reached a stage of semiequilibrium as far as the slag and the oxide in the steel is concerned. Special attention is paid to the rate at which the carbon is oxidized and also to the amount of iron oxide in the finishing slag so that it can be assumed that when the deoxidation additions are made of silicon and manganese, that the final steel in the ladle will contain a certain iron oxide content. Knowing the oxide content and the temperature, the aluminum can be added in the open hearth ladle to produce the fine grain steel if required. The addition of the aluminum in the ladle is generally made by the use of stick aluminum which should be carefully added to insure lower oxidation losses. Aluminum alloys such as silicon-aluminum-manganese, iron-aluminum-silicon, and iron-aluminum alloys have all been used to obtain a better control of the aluminum addition, although the common practice is still to use stick aluminum which is thrown into the ladle by hand as the ladle is being filled.

In the basic open hearth furnace, the usual addition required to meet a fine grained specification varies from 12 oz. to 2 lb. per ton. The usual minimum addition for a fine grained steel is approximately 1 lb. per ton, although where the maximum effect is required additions up to 32 oz. are not uncommon. It has been observed that as the addition of aluminum increases above 32 oz. per ton that there is no further increase in the grain refining effect and, in fact, if the aluminum addition is greatly increased above this point that there is a decided tendency to produce coarse grained steels. The aluminum cannot be considered to have a straight line

effect on the grain refinement, but reaches a maximum at approximately 32 oz. per ton and from then on decreases rapidly in its grain refining effect. It has been found that the manner of the addition of the aluminum has an important effect on the amount required and that where the aluminum is so added that it melts below the surface of the steel bath much less aluminum is actually required. This is an important factor in determining the amount of aluminum required and it is quite evident that much lower amounts of aluminum are necessary than is the case where stick aluminum is added to the open ladle.

Table I

Effect of Aluminum Addition on Grain Size in Commercial Heats—(Epstein, Nead, and Washburn)

Ladle C	Analysis, %—		Furnace Additions	Aluminum— Additions, oz. per Ton		Grain Size— Medium, Large, or Small		
	Mn	Si		Ladle	Mold	2-3	Mixed	5-7
0.19	0.44	0.10	Si-Mn	12	...	•		
0.19	0.39	0.10	Spiegel + Fe-Si	..	2.6		•	
0.22	0.47	0.12	Spiegel + Fe-Si	16	...			•

0.78	0.68	0.15	16	...			•

In the basic electric furnace, the additions of aluminum required to obtain a fine grained type are usually somewhat less than in the open hearth depending upon the character of the charge and the type of slag used. Due to the variation in furnace condition and the degree of deoxidation, it is impossible to give any hard and fast rule as to the exact amount of aluminum which must be added to produce a fine grained heat.

The literature does not contain many references to the specific use of aluminum in steel making practice. Epstein, Nead, and Washburn,² as well as Epstein and Rawdon,³ and Herty⁴ and his associates, have discussed the specific effect of given amounts of aluminum added to commercial heats, and the reader is referred to these papers for examples of the effect of specific additions of aluminum in the ladle and also in the mold on the grain size of the finished steel. The reaction of deoxidation with aluminum is discussed in reference 4.

With the exception of certain heats of structural and rimmed steel, aluminum is added to practically every heat of steel to some extent, except where the specifications require the coarsest possible grain size and even in such cases special attention must be given to the slag condition, and rate of carbon elimination.

Aluminum is an extremely important addition to carbon steels. It is also of almost equal importance in alloy steels and particularly in steels which are used for parts where minimum distortion, due to quenching stresses, is important, and in parts which are subjected to suddenly applied loads. The aluminum addition is of the greatest importance in gear steels which do not contain vanadium and practically every specification for these steels today requires the use of a carefully regulated addition of aluminum.

How the aluminum acts to cause this variation in properties is, at the present time, a more or less controversial subject, there being apparently two schools of thought. One of them attributes the relation between the grain size and the aluminum addition to a dispersion of alumina particles of submicroscopic but critical size, which act as nuclei of crystallization and interfere with the normal grain growth.

The other school of thought believes that the alumina theory of grain size con-

trol is not satisfactory and that the aluminum effect on grain size is due to its effect on the solubility of constituents such as carbides and nitrides.

According to Bain,⁵ the aluminum acts indirectly by forming submicroscopic, uniformly dispensed particles of alumina which act as obstructing agents in restricting grain growth. The hardenability varies with the grain size so that the aluminum in the oxidized form, by restricting grain growth, tends to indirectly reduce the hardenability of the steel to which it is added.

On the other hand, there are some metallurgists who do not believe that the alumina can in itself be the final answer to the effect of aluminum in restricting grain growth. Whether the aluminum acts directly or indirectly to cause the variation in characteristics is discussed by the writer in the Tenth Annual Campbell Memorial Lecture, and a hypothesis is offered suggesting metallic aluminum in solution and its effect on carbide coalescence as a cause of grain growth inhibition and pearlite divorce.

Schane⁶ expresses himself as believing that the restriction of grain growth in the fine grain steel cannot be satisfactorily explained by the oxide dispersion theory.

Scott⁷ shows that steel made from highly purified iron and known to be extremely low in oxygen content is fine grained after an aluminum addition, whereas other alloys made from purified iron without the addition of aluminum developed relatively a much coarser structure on heating slightly above the A_c .

In a paper on grain size and quality of steel by Ohman,⁸ together with comments by other prominent Swedish metallurgists, there is some discussion as to the reaction of aluminum and a considerable difference of opinion prevails as to the manner in which aluminum acts to promote grain growth restriction.

The common practice in this country is to add aluminum in the ladle, whereas, according to Ohman, the Swedish practice is to add it in the mold. Epstein shows that the mold addition of aluminum is apparently more effective in producing fine grain than the ladle addition, and theoretically the mold addition should be the most economical. Experience has shown that apparently more satisfactory results are obtained in large basic open hearth heats by a ladle addition.

While the aluminum addition is an important part of making carbon and alloy steel, there is still much work to be done to improve the results which are obtained. Considerable study is being given to the timing of the addition and to the method of making the addition, and there is no doubt but that this will result in a more highly developed control of open hearth heats.

Ingot and Pouring Practice

By G. A. Dornin*

General—After the furnace operations are complete the next step in producing a heat of steel is to get the metal into a solid homogeneous casting. In foundry practice, the casting will be of approximately finished size and shape. In ingot practice, the casting will take the form of a chilled ingot, which is to be rolled or forged into the final form. Regardless of the steel making process used, the procedure after the metal leaves the furnace consists of two distinct steps, first, tapping the heat into a container, called a *ladle*, and second, pouring from the ladle into molds having the size and shape of the ingot desired.¹

Ladle Practice—The function of the ladle is to act as a container or reservoir for the molten steel after it leaves the furnace. From the ladle the molten steel is poured into the mold. As steel practices and furnace capacities differ greatly, so also do the character and size of ladles differ to fit the various operating conditions. Steel ladles vary in size from approximately 100 lb., typified by the small hand-shank ladles used in foundries, to 100 tons, the usual size employed in large open hearth plants. In type, they fall under two general classes: *lip pour*, and *bottom pour*.

Lip Pour Ladles—This ladle is used in steel foundries, and in some Bessemer plants, and as the name signifies, it is constructed so that the metal is poured over the lip by tilting the ladle. It usually consists in a bucket-shaped shell of steel plate, having trunnions on the sides for engagement with a crane bail. The shell is lined with a layer of special refractory fire brick, or a mortar of ganister, clay, or sometimes magnesia. In practice the metal is tapped from the furnace, the slag being allowed to run on top to act as a cover. In pouring into molds, the ladle is tilted on the trunnions, usually by means of a worm and gear, the metal running over the lip, while the slag is held back. Small shank ladles often used in the foundry are simply steel pots lined with foundry sand or clay and properly dried. A modification of the lip pour ladle is the so-called tea pot ladle, in which an independent spout or tube is built down through the lining so as to connect at the bottom. This allows lip pouring in such a way as to draw the metal from the bottom of the ladle, thus avoiding contamination by the slag. This type of ladle is convenient in foundries handling basic steel, and particularly high manganese steel, which is notably corrosive on stoppers and nozzles.

Bottom Pour Ladle—This ladle has a steel shell of much the same shape as the lip pour ladle. It has trunnions for either hanging on a crane by means of a bail or for holding in a carriage or a buggy. Bottom pour ladles are usually lined with brick, sometimes used bare, and sometimes with a plaster of fire clay over the surface. The shell has a hole in the bottom close to the rim in which is inserted a refractory *nozzle* made of clay, graphite-clay or magnesia. Into this nozzle fits a *stopper* or *plug* made of a graphite-clay mixture. This stopper is held on a steel stopper rod which is protected by clay sleeves and extends vertically through the bath of metal. The top end of the rod protruding above the top of the ladle is fastened to a goose-neck extending over the side of the ladle which is raised and lowered by a lever. By this arrangement the flow of metal through the nozzle can be controlled. The sizes and types of nozzles and stoppers vary to suit specific purposes. In all cases the primary purpose is to deliver a smooth stream at the proper rate and temperature with the minimum amount of erosion of the stopper parts. Fig. 1 shows the section of a bottom pour ladle.

Operation—All ladles must be carefully dried before tapping the metal and in some cases, particularly in the smaller sized ladles, not only dried, but heated to a good red heat. In the case of the bottom pour ladle, the stopper is set when the ladle is cold, then unlocked from the rigging, and the ladle and stopper heated separately. When the steel is ready to tap, the stopper is keyed into the ladle, pulled tight into the nozzle, and held there with a set screw on the saddle of the

*Prepared for the Subcommittee on Melting by G. A. Dornin, Baltimore. The membership of the subcommittee was as follows: G. V. Luerssen, Chairman; G. A. Dornin, J. P. Gill, Dr. C. H. Hetty, Jr., O. K. Parmiter, and Dr. G. B. Waterhouse.

¹There are two possible exceptions, namely, in the crucible process, where it is sometimes customary to pour direct from the pot into the mold, by what is known as single practice, and in the high frequency induction furnace, where it is sometimes the practice to pour from the furnace direct into the mold.

stopper rigging. The stopper is then tried for tightness by means of a handful of sand thrown around the stopper head. In open hearth and arc electric practice, the ladle is carried by crane, and held under the spout of the furnace for tapping. Usually in the open hearth, and sometimes in the electric furnace, additions of deoxidizers or recarburizers are added to the ladle during the tapping. In Bessemer practice, the ladle is carried to the converter by a crane. The converter is tilted to tap into the ladle, and the necessary recarburizer additions are made during the transfer. When ladles are used in the crucible practice, they are called mixing ladles. They are supported on carriages or buggies running on rails straddling the pouring pit which contains the molds. The ladle is then run to some convenient point to which the individual crucibles are taken and teemed by hand with tongs into the ladle.

In all cases where the entire heat of steel has been tapped or transferred into the ladle, it is assumed to be at the proper temperature for pouring, or a somewhat higher temperature, uniform throughout, and covered with a slag blanket to protect the metal from oxidation and chilling by the air. If the temperature is too high, the ladle is held for a length of time calculated to cool it to the proper temperature. The metal is then poured into the molds.

After pouring the ladle is immediately dumped to clean out slag and residual metal, and cooled off, often with water. When cold the ladle is chipped free of slag and metal preparatory to repatching the lining. Sometimes when the metal is cold, a shell of steel, known as a *skull*, is left in the ladle. This must be removed, and often causes quite large repairs, because it tends to pull with it much of the refractory lining with which it is in contact. The amount of skull left in the ladle is often taken as an indication of the temperature of the metal.

When the ladle has been cleaned of slag and metal, it is patched with mortar and sometimes with brick, and a new nozzle and stopper set. It is then ready for drying for the next heat. With minor repairs after each heat, brick lined ladles run a limited number of heats per lining, after which the inner course of brick must be entirely torn out and replaced.

Fig. 1—Section of a Bottom Pour Ladle (Boylston).

Ingot Practice—Assuming the heat of steel in the ladle to be at the proper pouring temperature, the process of pouring into the molds to form a sound ingot may appear at first glance to be a very simple matter. On the contrary the operation involves a great many complex reactions, the control of which is extremely important since in pouring the ingot the steel maker is virtually laying the foundation for everything which comes after. To comprehend this clearly, it is necessary to look briefly into the mechanism of the freezing of steel.

Freezing of Steel—In the molten condition steel is practically a uniform liquid, every part being like every other part. The various elements in addition to iron, such as carbon, manganese, silicon, phosphorus, sulphur, chromium, nickel and vanadium, are all uniformly in solution in the iron or practically so. However, upon freezing, the steel no longer has this complete uniformity. The reason for this is that like all other metals, steel crystallizes upon freezing, and in so doing, solidifies selectively. Solidification begins with the formation of crystals rich in the element which raises the freezing point of the alloy. The liquid left between the crystals is rich in those elements which lower the melting point of the alloy. If cooling is fast, they are quickly trapped between the original crystals, which on account of their tree-like form, are called dendrites, and in this condition are not harmful, since they are well distributed and in a condition which can readily be broken up in hot working. However, if cooling is quite slow, the low melting constituents will remain liquid for a sufficient length of time to allow

them to gather into certain parts of the ingot, particularly the axis. The gathering of these low melting constituents is called segregation. The extent and location of such segregations depend upon the speed of freezing, which in turn depends upon the sectional size of the ingot, pouring temperature, rate of pouring, and the design of the mold.

Upon freezing steel contracts or shrinks, so if the mold is poured full of molten steel, it will no longer be full after the steel is solidified. It will be found that the steel has not simply settled down, leaving an air space above it, but that the location and shape of this air space or *shrinkage cavity* depends largely upon the shape and design of the mold.

Mechanism of Freezing—The first metal freezing against the mold wall shrinks slowly, and this shrinkage is immediately filled by the molten metal in contact with it. Each succeeding layer freezing parallel to the mold surface similarly shrinks and robs molten metal from the center. In a cylindrical or prismatic mold, the steel freezes progressively to the walls. The molten pool in the center gradually sinks downward as it feeds these shrinking walls. This continues as long as the chilling effect of the mold wall is felt in the molten pool. When this effect is no longer felt, the molten metal freezes slowly throughout, and shrinks downward. The net result is an ingot with sound walls, with an axial cavity, or pipe, extending a considerable distance downward. This pipe can be made to extend deeper into the ingot by designing the mold large at the bottom and small at the top (big end down), and it can be made much shallower by reversing the procedure and designing the mold big end up. Fig. 2 shows sections of big end up and big end down molds and the difference in freezing behavior.

Fig. 2—Section of Big End Up and Big End Down Molds.

Another result of the shrinkage of steel during freezing is the behavior of the surface metal. The first molten metal coming in contact with the mold wall freezes instantly. As it does so, it also shrinks and the surface metal tends to pull away from the mold wall, leaving an air gap. Therefore, the shell of metal is now supporting the molten metal inside and is no longer in direct contact with the mold wall. This has two disadvantages: 1. It greatly reduces the chilling effect of the mold; and 2. it introduces the danger of the molten metal rupturing the shell, resulting in bleeding, and consequently a rough or cracked ingot. The round sectioned mold introduces the greatest hazard in this respect. The square mold is a considerable improvement over the round, and the fluted or corrugated mold is an additional improvement over the square.

Therefore, the design of the mold is a very important factor in the production of sound ingots. It should be mentioned, however, that the conditions described can be modified by adjustments in the pouring temperature and pouring rate, factors which must not be overlooked when discussing shrinkage and segregation.

Another characteristic of steel is that it liberates a certain amount of absorbed gas during freezing. The amount depends upon the method of manufacture. Killed steel liberates a comparatively small amount, but open or rimming steel evolves quite large quantities of gas. The evolution of this gas must be controlled by proper deoxidation methods and a suitable amount of chill to keep the resulting blowholes deep under the surface where they will be comparatively harmless.

Thus far the conditions considered affect the internal structure of the ingot. The surface condition is of equal importance, as this determines the amount of expensive chipping or grinding which must be done on the resulting billet to insure a finished bar or forging free from surface defects. To produce a good ingot surface requires a good mold surface, and a minimum of splashing during the pouring of the ingot. This is sometimes accomplished by pouring the ingots from the bottom by means of a gate or runner, often in groups. This practice is called bottom pouring and is used principally in the production of forging ingots. The use of mold washes also improves ingot surface.

Mold Design—Ingot molds are generally cast iron although a few steel molds have been used with indifferent success. Water cooled molds have also been used to a limited extent, although these are still in the experimental stage. The small molds ranging from 3-6 in. sq. are often of the split or two-piece type to facilitate stripping. Molds over 6 in. are usually of the solid type, although some larger split molds are used. The solid molds fall into two general classes: Big end up and big end down. Big end down molds have the advantages of lower first cost and easier stripping. Big end up molds have the advantage of higher yields and sounder steel. Molds may be of various shapes such as square, rectangular, corrugated round, 8-sides fluted, or 12-sides. Big end down molds are open at both ends and are set upon a cast iron or copper stool which forms the bottom of the mold. Big end up molds usually have a round hole in the bottom which is closed with a tapered plug, as in the Gathmann type.

Setting the Molds—The method of setting the mold preparatory to pouring varies in different plants. In most open hearth plants molds are set on buggies, three to each car, and are spotted along a pouring platform on which the ladle man stands during the pouring of a heat. In some plants the molds are set on the floor, while in others they are set in pits so that the ladle man needs no platform.

Molds are carefully cleaned, then usually coated with a mold wash, either a tar compound or whitewash, or smoked with burned rosin. In many plants a *hot top* is used on the top of the mold to eliminate pipe. This is an insulating shell made of brick or sand which keeps a reservoir of hot metal in the top of the ingot, thus the pipe cavity is progressively fed as the ingot shrinks during freezing.

In bottom pouring, the stools are especially designed with a hole in the center into which is inserted a brick cup. This cup is connected to a built up tube of brick, known as a runner, which in turn is elbowed to a vertical brick runner into which the metal is poured.

Pouring Operation—The ladle is spotted over the properly set mold, or over the runner in bottom pouring. The steel is carefully poured at the proper rate which is often determined by a watch. Sometimes instead of pouring direct into the mold, the steel is poured into a pouring box which has one or more nozzles in the bottom. This pouring box is used for the purpose of reducing pressure and thus eliminating splashing during the pouring of the ingot.

Where hot tops are used, it is often the practice immediately after the ingot has been poured to cover the top with some insulating material to assist in keeping the top metal molten. When the ingots are entirely frozen, or *set*, they are removed from the mold, or *stripped*. In the case of car type molds special stripping cranes are in use, adapted either to big end up or big end down practice. With the ordinary pit practice, stripping is done by hand with the assistance of the crane.

The cooling of the ingot after stripping, particularly in the higher alloy steels, is of considerable importance and must be done carefully to prevent cracks. Usually when the ingots are not taken hot direct to a soaking pit, they are buried in ashes or other insulating material to insure slow cooling.

The Manufacture of Hot and Cold Rolled Strip and Sheets*

Composition Suitable for the Various Grades—Low carbon steels are generally considered those with a carbon content less than 0.20%. Often those unfamiliar with the sheet and tin plate industry are inclined to regard variations in composition within the low carbon range as relatively unimportant, and of only minor influence on the physical characteristics of the steel. In fact, it might be pertinent to state that the whole field of low carbon steel, particularly as it relates to the manufacture of sheets and tin plate, has been accorded much less attention on the part of educational and research institutions than its economic importance deserves.

Actually, what might be considered small differences in carbon, manganese, phosphorus, and sulphur may spell success or failure in the ultimate use for which the product is intended. The succeeding paragraphs will attempt to explain, in a general way, the influence of the common elements in steel, and what considerations must be taken into account when producing sheets for specific requirements, for, as in so many other branches of the steel industry, it is impossible in most instances to ship stock sheets; the peculiarities of each requirement must be analyzed, and a special product manufactured to meet it.

Hot Rolled Sheets—For convenience, the product of the old style hand sheet mills will be called "hot rolled sheets" to differentiate them from hot rolled strip sheets as produced on a continuous hot strip mill, and cold reduced sheets as produced on the continuous cold mills.

Formerly, the hot sheet mills rolled all of their product from sheet bar. With the advent of the continuous hot strip mills, many producers with both types of equipment commenced to substitute strip packs for the intermediate breakdowns rolled from bar. This resulted in improved surface, more uniform gage, increased production, and, to some extent, relieved certain limitations as to chemistry. However, the same general principles still apply.

In the pack rolling of sheets in the lighter gages (20 gage and lighter), the pressure of the rolls tends to weld the sheets together. This effect can be counteracted by adding phosphorus to the steel, which is sometimes done, particularly for 26 gage and lighter. However, phosphorus is a hardening element, and, in work where ease of forming or deep drawing are a requisite, it is often a hindrance.

Manganese is important in improving surface toughness in drawing, but it apparently can contribute to blisters in pickling and galvanizing when its presence exceeds certain limits. In rimmed steel, from which the major tonnage of sheets is now rolled, the surface tends to be open or porous in pack rolling. If the manganese falls much below 0.20%, this characteristic is accentuated, and, where surface is of prime importance, it is objectionable.

Carbon acts as a deterrent to grain growth in box annealing, and, except for vitreous enameling sheets, it is desirable to keep the carbon content over 0.03% by check analysis.

Automobile sheets produced on the hand mills are rolled from rimmed steel with a ladle analysis approximating 0.05-0.08% carbon, 0.25-0.50% manganese, phosphorus under 0.030%, and sulphur under 0.050%. Here, the manganese will assist in producing a tight surface; the carbon and manganese together will result in a fairly small grain size with the desired toughness and ductility, and, after drawing, the stamping will have a smooth finish.

Typical analyses for various products are as follows:

	Carbon, %	Manganese, %	Phosphorus, %	Sulphur, %	Copper, %
Ordinary requirements, stock, mild forming.....	0.05-0.08	0.20-0.35	Depending on gage	Low as Possible	As Specified
Deep drawing and automobile sheets	0.05-0.08	0.25-0.50	0.030 Max.	"	
Surface important, painting, lithographing	0.05-0.08	0.25-0.50	Depending on gage	"	As Specified
Galvanizing	0.04-0.07	0.15-0.30	"	"	"
Vitreous enameling.....	0.03 Max.	0.10 Max.	Low as poss.	"	

Higher carbon steels are used for frames and other structural parts, but as the carbon is increased the workability decreases, and 0.35% carbon appears to be the

*Prepared by the Subcommittee on Sheet and Strip. The membership was as follows: J. H. Nead, Chairman; E. L. Kerschbaum, J. E. Angle, T. F. Oil, R. W. E. Leiter.

upper limit of a steel which may be bent cold to a right angle around a radius equal to the thickness of the sheet. This limit can be raised by suitable annealing practice.

In the discussion of types of steel for various products, certain modifications of the above will be cited, since killed steels, in particular instances, give much better results than rimmed.

Hot Rolled Strip Sheets—Hot rolled strip in sheet widths (24 in. and wider) is commonly rolled as light as 18 gage. With proper slab conditioning, and good mill practice, a smooth tight surface can be obtained regardless of the analysis of the steel. Therefore, certain chemical limitations are removed.

Rimmed steel is generally used for hot rolled strip. Typical analyses will approximate 0.05-0.08 carbon, 0.25-0.50 manganese, 0.03 phosphorus, max., by ladle analysis. Where only mild forming is involved, a certain latitude is permissible, particularly in respect to phosphorus and sulphur. In sheets for deep drawing, the phosphorus, in particular, and the sulphur are held as low as possible. Further variations in physical properties necessary to fit the requirement are usually secured by subsequent treatments such as normalizing, open annealing, box annealing, cold rolling, or pickling.

Cold Reduced Sheets—Steel quality and chemical analysis are probably of more importance in producing a successful deep drawing sheet by the cold reduction process than by hot rolling. This may be due partly to the fact that cold reduced sheets, after final temper rolling, are in a state of unstable equilibrium which increases the sensitivity of the steel to certain variables. Also of importance, no doubt, is the fact that the difference between success and failure may be the loss of one stamping, more or less, out of a hundred. There is no question that the most careful control from blast furnace to final processing is necessary for the manufacture of a consistently satisfactory deep drawing sheet.

Factors to be considered in selecting the analysis to be used for cold reduced deep drawing sheets are:

(a) *Size and Shape of the Drawn Part*—Large deep stampings such as automobile quarter panels require a relatively soft, and, at the same time, ductile sheet. Owing to the size and awkward shape of the part, a stiff or hard steel will wrinkle in the die, and, if increased hold down pressure is applied, breakage will usually result. For such work, the carbon and manganese may be held to the low side of a 0.05-0.08 carbon, 0.25-0.40 manganese specification. In this particular respect, cold rolled sheets produced on the hand mills, with a normalize and box anneal treatment, have an advantage over the cold reduced box anneal sheet, since, for the same analysis, they sometimes tend to be softer; but other considerations, such as perfection of surface, and especially uniformity of thickness, tend to offset any possible advantage of greater softness.

Small deep stampings, in which wrinkling is not a hazard, permit of slightly higher manganese content with a resultant finer grain size and improved ductility.

(b) *Surface After Drawing*—In deep drawn parts, where surface is of importance, it is often necessary to exercise as much control as possible over the grain size of the finished product, since a relatively large grain will result in a type of "orange peel." Automobile fenders are a good example of a part where the surface after drawing demands a small grain. Expressed in terms of the A.S.T.M. grain size chart, a No. 7 or 8 grain is usually preferable. Although treatment is important in the control of grain size, manganese content is also important.

Phosphorus is especially harmful in deep drawing work, and is held as low as possible. Sulphur is generally believed to be detrimental in deep drawing sheets, but its effect is not so clearly known as is the case with phosphorus.

There appears to be an increasing demand for steels of the low alloy high strength type,¹ especially in the field of transportation.

These steels have a 50,000-60,000 psi. minimum yield strength, and 65,000-70,000 psi. minimum tensile strength; the maximum tensile strength will seldom exceed 85,000 psi. The minimum elongation is usually around 20%. These steels are more often found in the heavier gages, but recently sheets as light as 24 gage have been rolled.

Various elements and combinations of elements are used as strengtheners in this type of steel to obtain a proper balance. The ranges are as follows:

C	Mn	P	S	Si	Cr	Cu	Ni	Mo
0.12 Max.	0.20-1.00	Residual to 0.200	0.045 Max.	Residual to 1.00	None to 1.5	0.30-1.75	None to 2.25	None to 0.12

Types of Steel—The terms, "rimmed" or "killed," apply to the action, or lack of action, of the steel in the molds during solidification of the ingots. Steels containing up to 0.30% carbon can be either rimmed or killed, as desired; but above 0.30% carbon the steels are killed. Alloy steels, with the exception of copper-bearing steels, are usually "killed" or deoxidized in the furnace, ladle or molds.

Except for special analyses, rimming steel is used for the majority of sheet and strip applications. In certain work, such as deep drawing and forming, its softness and ductility are particularly well suited. There are other applications where the type of steel would make no particular difference; but, as might be expected, there are certain specifications where killed steel is to be preferred.

A rimmed steel is a natural steel in that the dissolved gases are allowed to separate as the liquid metal freezes, and rise to the surface in an effervescent action which is controlled by the addition of aluminum or other deoxidizers to the ladle or ingot. The rimming action progresses until the ingot is capped or freezes over the top. Its effect, when properly carried out, is to produce a thick skinned ingot with a heavy "rim" which may be hot rolled with a minimum of surface defects. The rimming action also reduces the carbon, and to a lesser extent the manganese, in the outer or rim portion of the ingot.

The factors controlling the rimming action are composition or analysis of the steel, furnace practice, and deoxidation practice in the ladle and the molds. A deep etched cross section of a piece of rimmed steel shows a characteristic rim and core (or segregate), except at the extreme lower part of the ingot. This segregation of metalloids accounts for variations in analysis found in different parts of a sheet or order.^{2, 3}

"Killed" steels are made by adding a sufficient quantity of the various deoxidizers to the furnace, ladle, or molds. The deoxidizing materials have a greater affinity for oxygen than iron or manganese, thus forming more stable compounds, and these may be partially eliminated during subsequent processing and cropping. As little gas is formed, either due to reactions or to gases coming out of solution: the ingot top freezes rapidly and the ingot solidifies as a comparatively homogeneous mass. Little segregation takes place; and analyses of the various parts of the ingot are more uniform than in a rimmed steel.

These characteristic differences in the two types of steels have certain effects on the sheet and strip produced from them. The rimmed steel has a thicker skin, which results in a sheet comparatively free from surface defects. A killed steel generally has a more sensitive skin which may or may not be ruptured during hot reduction in the mills from the ingot to the bar or slab, and this may result in either surface laminations or seams. For this reason, when surface is important, rimmed steels are almost universally used.

There are certain advantages in favor of the killed steels, such as uniformity of analysis; and a properly killed and processed steel is comparatively free from aging. However, for the same carbon and manganese content, the killed steel is harder than the rimmed steel.

In sheets hot rolled on the hand mills, killed steel is decidedly superior to rimmed in producing a smooth tight surface free from orange peel. Its use is, therefore, to be preferred for hot rolled annealed furniture stock, lithographing and japanning stock, and blued stove pipe sheets. The uniformity of its properties from edge to center also makes it desirable for stretcher leveling.

Its disadvantages lie in its somewhat higher hardness for the same analysis, and its susceptibility to seams and skin laminations.

In the heavier gages, such as are rolled on the hot strip mill, many specifications require check analyses. Here, killed steels are often used because the sheet analysis can usually be depended upon to correspond closely to the ladle analysis.

Killed steels are not widely used at present in cold reduced sheets except, perhaps, for stretcher leveling. Even here, equally good results can be secured with rimmed steel by heavy top cropping, or diverting the top portion of the ingot to other work.

The characteristics of rimmed steel leave much to be desired, especially in deep drawing cold reduced sheets. Although with present methods of control greater uniformity from heat to heat is now possible, there still remains the variation in the ingot (top to bottom as well as rim to core), and the variation from ingot to ingot within a heat. Differences between top and bottom may be somewhat lessened if desired by diverting the top portion of the ingot to other work. However, such diversion is not always economical and, at best, is not desirable. In straightaway rolling,

the rimmed area is usually in the hold down of the die where it is not detrimental.

Perhaps the most objectionable characteristic of rimmed steel in cold reduced sheets is the aging which occurs after the final temper rolling. This exhibits itself in the return of the tendency to stretcher strain, in an appreciable increase in hardness and yield strength, and in a decided decrease in ductility, as measured by cup tests, and elongation in tensile testing. Aging begins immediately after the final cold working, but it is usually not serious until after 3 or 4 weeks. The extent to which it affects performance depends to a considerable extent on the properties of the steel at the time of temper rolling. For example, a 20 gage sheet with 45 Rockwell B hardness and .42 Olsen cup may age harden to 50 Rockwell and .400 Olsen, and still draw satisfactorily. However, if the initial Rockwell had been 50 and the Olsen .400, and the same amount of aging had occurred, it is possible that breakage would result on certain difficult jobs.

The theory of age hardening has been fairly well established, and nonaging steels have been manufactured. It is difficult, however, to produce a soft nonaging steel suitable for sheets without excessive losses due to surface defects, and which responds satisfactorily to annealing.

In hot dip galvanizing, tinning, or terne coating, the temperature of the metal is high enough to effect complete aging in many cases. This may or may not be detrimental, depending on the use. It can be overcome by special treatments which eliminate the final temper rolling, or there are requirements which can best be met by using a low metalloid steel. In certain tin plate applications, where stiffness and rigidity are necessary, rimmed or killed Bessemer steel is often used.

Classification of Sheet and Strip—The following table gives the size range of sheet and strip. Due to increased accuracy of the strip mill, permitting wider sheets, the difference between sheet and strip based on widths has become an arbitrary figure.

Standard Classification of Flat Rolled Carbon Steel

Width, Inch	Thickness, inch						
	.2500 or Thicker	2499 to 1875	1874 to 0568	0567 to 0344	.0343 to 0255	0254 to .0142	.0141 or Thinner
<i>Hot Rolled</i>							
Up to 3½ inclusive	Bar	Strip	Strip	Strip	Strip	Sheet	Sheet
Over 3½-6 inclusive	Bar	Strip	Strip	Strip	Sheet	Sheet	Sheet
Over 6-12 inclusive	Plate	Strip	Strip	Sheet	Sheet	Sheet	Sheet
Over 12-32 inclusive	Plate	Sheet	Sheet	Sheet	Sheet	Sheet	T.M. Black
Over 32-48 inclusive	Plate	Sheet	Sheet	Sheet	Sheet	Sheet	Sheet
Over 48.....	Plate	Plate	Sheet	Sheet	Sheet	Sheet
<i>Cold Rolled</i>							
Up to 12 inclusive	Strip	Strip					
Over 12-24 inclusive	Strip ¹	Strip ¹					
Over 24-32 inclusive	Sheet ²	T.M. Black ²					
Over 32.....	Sheet	T.M. Black					
		Sheet					

¹ If special edge or finish, or temper as in A.S.T.M. Spec. A-109.

² If no special edge, finish, or temper.

Hot Rolling—Sheets and strip can either be hot rolled directly to the desired thickness or hot rolled to an intermediate thickness and then cold rolled to the desired thickness. The latter process is used if improved surface finish or special temper and properties are desired. Hot rolling is here classified as including rolling operations in which the material is heated before passing between the rolls. Sheets are hot rolled by a number of methods: 1. On broad hot strip mills from slabs; 2. On hand mills from sheet bar; and 3. On hand mills from broad strip sheared breakdowns.

1. Broad Hot Strip Practice—The rolling of broad hot strip or "sheets in coils" has been a continuous development since 1927, when the first mill was built capable of rolling a strip over 24 in. wide. The strip process differs from the sheet process in that in the former the reduction is performed in long lengths, which are subsequently cut up or coiled, while in the latter the reductions are performed in unit lengths or a small multiple. In strip rolling a slab ingot is cast and rolled to a slab of 3-6 in. in thickness and of a width and length suitable for charging into the slab

reheating furnace, where it is brought up to a temperature of 2200-2300°F. for rolling.

The broad strip mills consist of a roughing train and finishing train set in tandem, the finishing train being set on close centers so that the strip is in all of the finishing stands at the same time. The number of roll stands can be varied to suit the variety of products produced in any given mill, but usually vary from 4-7 roughing stands and 4-6 finishing stands. The roughing train usually consists of a two high scale breaker to break up the scale on the surface of the slab, a spreading mill to spread the slab to the desired width of strip, after which it is turned 90° and squeezed to straighten the edges. The slab is then rolled to the desired rough bar thickness in the balance of the roughing mills which are usually of the four high type and equipped with vertical edging rolls to hold an accurate width in the bar. In the roughing reductions, the slabs are usually sprayed with high pressure water to descale the surface of the slab as it progresses through the mills. As a modification in practice, the slab can be rolled to a rough down bar on a reversing universal mill. After roughing, the bar goes through another scale breaker and high pressure spray and into the four high hot strip stands where it is reduced to the desired thickness. These mills are so synchronized as to speed that each successive mill takes the strip at exactly the same speed that the preceding mill is delivering. The delivery speed varies from 1000-2100 f.p.m. The finishing temperature can be varied over a considerable range by varying the slab heating temperature and holding time ahead of the strip mill. In general, the finishing temperature varies from 1300-1600°F. and must be closely controlled wherever it is desired in order to keep uniform thickness throughout the length.

After the strip is delivered from the last stand, it can be either coiled or cut to length, flattened by leveling, and piled. It must be coiled or piled at a temperature sufficiently low so that appreciable grain growth^a does not take place.

The product of the hot strip mill has a wide variety of uses. It may be cut as breakdowns for a hot sheet mill if a thinner gage is desired than can be produced on the hot strip mill. It may be shipped directly after cutting and leveling, or after normalizing and pickling if better properties are necessary for the particular requirements under consideration. After pickling in coils, it may be used for the production of thinner gages than can be rolled directly on the hot strip mill by continuous cold reduction processes and also for applications where a better and smoother surface than can be obtained on a hot strip mill is required.

The process for narrow strip is similar to broad strip, except that lighter equipment can be used and less power is needed. The wider the strip desired, the more massive the equipment must be and the greater the power requirements, which are approximately 400-500 connected hp. per in. of width capacity.

2. Sheet Bar Practice—The sheet bar practice for the production of hot rolled sheets involves the rolling of an ingot to a rectangular sheet bar which is usually 8 or 12 in. in width and of a thickness that will allow cross rolling on a hot mill to the desired thickness and length. The sheet bar is cut so that its length is slightly greater than the width of the desired sheet. The hot mill consists of two stands of rolls, known as the roughing and the finishing stands, and two furnaces known as the "pair" furnace (so named because the bars are withdrawn and roughed out in pairs) and the reheating furnace where, after matching the rough outs are reheated for finishing. The rolls are of chilled iron and are driven by constant speed motors, or in some extremely old installations, by a steam engine. The sheet bars are heated in the pair furnace to a temperature of 1300-1600°F., depending on the grade of steel and surface finish required, and rolled in pairs to a breakdown gage using single passes and then matching the bars and rolling in pairs until the breakdown gage is reached. At this point the breakdowns are matched, reheated, and finished to the desired sheet thickness. This general method can be modified by pickling the bars and breakdowns to produce a smoother and more uniform surface finish. Also, sheets 0.025 in. and thinner are usually made "double," that is, the matched breakdowns are folded over on themselves before reheating.

After hot rolling to the desired thickness, the sheets in packs are trimmed to the desired dimensions and separated and are ready for further processing operations.

3. Sheared Breakdown Practice—This process is somewhat like the sheet bar practice except that the breakdowns are sheared from broad hot rolled strip of a width slightly greater than that of the desired sheet and of a length sufficient to make a sheet of the desired gage and length. The breakdown operation is eliminated and consequently only one stand of finishing rolls is necessary. This practice lends itself readily to the utilization of continuous pack heating furnaces and mechanized

feeding and catching tables. It also lends itself to the use of single three high mills which roll both under and over the middle roll (from both sides of the mill) with greater reductions and increased speed and also the same type three high mills set up in a tandem train. Pickling the sheared breakdowns before hot rolling improves the smoothness and uniformity of the surface finish. As in the sheet bar practice, after hot rolling the sheets are trimmed on all sides and separated and are ready for further processing.

Cold Rolling—Sheets and strip are cold reduced to the desired thickness for several reasons: 1. To obtain the desired surface finish; 2. To impart desired physical properties; and 3. To make gages thinner than the hot strip mill can produce economically.

The cold reduction can be accomplished either in unit lengths or in coils, but it is more economical from a yield standpoint to perform the reduction in coils.

There are numerous types of equipment for performing the cold reduction, but as in the case of hot strip mills, the wider the material to be cold reduced and the thinner the desired gage, the more rigid the mill, and the more power required. In narrow widths (under 20 in.) the reductions can be performed conveniently on two-high mills, but in the wider widths the four-high mill is used almost entirely. As the width is increased or the thickness decreased, the diameter of the backing up rolls is increased. The working roll diameter is kept as large as is compatible with the maximum screw pressure allowable.

The amount of cold reduction performed is governed largely by the application under consideration. For example, sheets and strips for drawing applications are cold reduced from 30-70% in thickness. Tin plate may be reduced as much as 90% in thickness. Increasing amounts of cold reduction will tend to make the resulting sheet and strip finer grained and harder after annealing.

Equipment for cold reducing steel sheets and strips is available which makes use of the following applications of power to effect the desired reduction: (1) All power applied to the working rolls; (2) all power applied as forward and back tension; (3) power applied partly to the working rolls and partly as forward tension; and (4) power applied to the working rolls, also as forward and back tension.

1. *All Power on Working Rolls*—The cold tandem sheet mill or single stand mill for the reduction of strip breakdowns in units is an example of this method of application of power. This method involves the production of more scrap due to the multiplicity of ends sheared from the sheets when heavy reductions are performed. This method is also used to a great extent in skin rolling sheets after annealing to remove the tendency to form stretcher strains when drawn. Skin rolling involves little reduction in thickness of the section.

2. *All Power Applied as Forward and Back Tension*—This method of application of power is employed in the "Steckel mill" which is a four high mill with small working rolls for rolling coiled material. This type of mill is limited in the amount of cold reduction that can be taken in a given pass, but is built to reverse and can reduce any number of passes and to any practical thickness desired. The small diameter working rolls present a small surface area and hence wear rapidly and must be replaced frequently or whenever the surface of the strip being rolled is unsatisfactory. This mill is rather popular for extremely hard or thin materials and high priced specialties with extremely close tolerances in thickness variation.

3. *Power Applied Partly to the Working Rolls and Partly as Forward Tension*—This method of reduction is typical of by far the greater number of tandem cold reduction mills utilizing coil stock. In general, the reduction mill is made up from 3-5 tandem stands of four high mills with a powerful reel producing forward tension. The capacity of this type mill is governed largely by the thickness and width being rolled, and the delivery speed of the mill. Cold mills delivering tin plate gages deliver up to 1500 f.p.m., whereas the heavier sheet gages are usually delivered up to 700 f.p.m. This type mill has the advantage of high capacity and low labor and roll cost, although the investment is high. Disadvantages are lack of flexibility for rapid section changes and the fact that material being rolled receives a fixed and limited number of passes.

4. *Power Applied to Working Rolls, also as Forward and Back Tension*—This application of power is exemplified by the single stand reversing mill. This type mill differs radically from the Steckel mill in that it is not limited in the amount of reduction per pass as is the Steckel type. This mill is advantageous from the standpoint of flexibility of number of passes and requires less investment cost and floor space than a tandem mill. The energy expended in back tension is regenerated by

driving the back reel as a generator against the line load, the back tension also serving to reduce the screw pressure and the net energy required for the deformation. On the other hand, the investment per ton capacity, labor cost, and roll cost is higher than for a tandem mill.

Annealing of Sheets and Strips—It is necessary to perform some manner of annealing operation on hot reduced and cold reduced sheet and strip, unless a hard temper is desired. This may not be necessary on some hot rolled strip finished at 1500-1600°F. or over and coiled hot so that an annealing is accomplished in the coil. If the sheets are reduced to gage below the recrystallization temperature as they are on the sheet bar finishing mill or cold reduction practice, the grain structure is fragmented and plastically deformed by slip resulting in preferred orientation.

There are a number of softening operations used in sheet and strip production, the most important of which are: (1) The cold strain, low temperature recrystallization anneal; (2) the normalizing operation; and (3) the stress relieving anneal.

1. The Cold Strain, Low Temperature Recrystallization Anneal—This process may be used on material cold reduced in excess of 30% (includes hot rolled material finished at a low enough temperature to give the equivalent strain of material rolled cold). This type of annealing (also known as "processing annealing") is carried out by placing stacks of sheets or coils on a bottom or plate and then covering the pile. The charge is then heated to the desired temperature, which may vary from 1200-1400°F., and allowed to soak until the temperature is uniform throughout the charge, after which it is allowed to cool to the desired temperature before uncovering.

This annealing may be carried out in stationary furnaces in which the charge, including plate and cover, is inserted in the furnace for the necessary heating and soaking and then removed for cooling, or in the radiant tube type furnace in which the plate is stationary and the furnace is lifted from charge to charge for the necessary heating and soaking. The charge may vary from 5-100 tons, depending on the size sheet or strip and height of stack. The source of heat may be gas, coal, oil, or electricity.

Material that has been cold reduced or descaled before annealing is usually annealed in a protective atmosphere or "bright annealed" in order to prevent the formation of oxide on the sheet during the heating, soaking, and cooling cycle. This protective atmosphere is ordinarily produced by partially burning natural gas or butane to a gas composition that is slightly reducing to iron but will not break down further and deposit carbon at the annealing temperature. Most of the water vapor produced from the partial burning is removed from the protective gas by refrigeration. Material that is desired with an oxide finish is either annealed without the protective atmosphere or "steam blued" by adding steam under the cover after removal of the charge from the furnace when the temperature has dropped to 1000-1100°F.

2. Normalizing—The normalizing operation consists of heating the sheet or strip to a temperature above the upper critical or A_3 point (approximately 1650°F.) and cooling to room temperature. This recrystallizes and refines the grain structure through the medium of a phase transformation. The normalizing operation is utilized to the greatest extent on hot reduced material to produce improved drawing properties, as in many cases a low temperature box anneal would result in critical grain growth due to a low residual strain in the hot reduced product.

Normalizing furnaces for sheets are usually of the chain type, roller type, or walking beam type. Fuels may be gas, oil, or electricity. With electric furnaces or muffle types, it is possible to "bright normalize" by using an inert or a reducing atmosphere to protect the surface of the strip from oxidation.

The grain size and hardness of normalized material can be controlled within limits by varying the soaking time above the A_3 point and also the cooling rate from the A_3 to the A_1 point.¹⁰

3. Stress-Relieving Anneal—This annealing operation is a low temperature pack or box anneal utilized to remove the internal stresses, produced by the rapid cooling in the normalizing operation and in leveling or light rolling operations after normalizing, in order to improve the drawing properties. This operation is commonly known as a "second or white anneal" and is carried out in the same manner and with the same equipment as the cold strain box anneal except that the temperature of annealing is in the range of 950-1200°F. A protective atmosphere can be used under the cover to prevent oxidation or the charge may be steam blued as desired.

Typical values of physical properties of mild steel sheets and strips after the annealing operations referred to are given in the following tabulation:

	Yield Points, psi.	Tensile Strength, psi.	% Elong. in 2 in.	Rockwell	Olsen Cup (.040 thick)
Hot rolled (sheets)	50,000	68,000	10	B-70	.200
Hot rolled (cold strip)	45,000	55,000	30	B-60	.350
Hot rolled + normalize	38,000	52,000	32	B-55	.365
Hot rolled + 2nd anneal	30,000	48,000	38	B-50	.390
Hot rolled + cold reduced	85,000	85,000	4	B-90	.120
Hot rolled + bright anneal	28,000	45,000	42	B-45	.410
Hot rolled + normalized	40,000	54,000	30	B-60	.360
Hot rolled + normalized + 2nd anneal	32,000	50,000	38	B-52	.390

Surface Characteristics—The surface texture of sheets and strip can be varied between rather wide limits. For chromium plating and similar uses, a smooth bright surface is necessary, but for vitreous enameling and many drawing operations, a certain dullness or roughness of surface is more suitable. In the case of vitreous enameling, the roughness improves adherence; and in certain drawing operations where heavy pressures are developed, the duller type of surface draws better. It also appears to aid in the distribution of the draw. Minor surface imperfections and slight strains are not so noticeable on a dull surface as on a bright one. However, the surface should not be so dull that subsequent finishes will not cover.

The smooth finish can be obtained by grinding and polishing the rolls. The dull surface can be obtained in several ways. A chill cast or alloy cast iron roll can be dulled by acid etching the ground surface. This develops the dendritic structure by removing segregated areas, and leaves a pattern which can be imprinted on the surface of sheet or strip, resulting in a light dullness. This pattern will vary from roll to roll because of differences in the size of the dendrites.

Since a hardened steel roll does not have a massive structure which can be developed by etching, it is necessary to dull the roll by mechanical means. This is done with either sand or shot blasting equipment which can be controlled to give a uniform dullness of any desired degree by varying pressure and shot size. Because of the control over dullness by this process, it is also used to a large extent on chill cast rolls.

The surface can be dulled in the last stand of a tandem cold strip mill before annealing, and the sheet can be either skin rolled dull or bright after annealing; or the dullness can be applied to the bright sheet after annealing.

Metallic Coatings—Three types of metallic coatings are commercially applied to sheets or strip by steel manufacturers. These are zinc (galvanized sheets), tin, and terne, an alloy containing approximately 80% lead and 20% tin. In all three coatings, the hot dip method is commonly used, although sufficient work has been accomplished with the electrolytic coating of zinc and tin to indicate that it is commercially possible. For information about these methods, see the articles in this Handbook on Zinc Coatings and Tinning of Steel.

Testing and Inspection—*Drawing Factors and Hazards*—Appearances of a number of strips or sheets from different sources may be quite similar; but actually there are many ways of obtaining substantially the same appearance with major or minor variations in properties. Each mill is limited to a certain extent by its equipment; as the processing is modified, the properties of the product vary, and yet the material may make the part satisfactorily.

At present there are many variables in testing practice and it would be almost impossible to prepare "standards" in all tests which would meet all contingencies to the satisfaction of both producer and consumer. There are many cases of breakage in drawing operations where the material is not at fault. The die practice may be bad, due to poor design, improper clearance, too much deformation between anneals, improper hold down or drawing adjustments, or poor lubrication. In some cases, the sheet is of too light gage for the amount of deformation it is expected to stand.

Winlock and Kelley⁴ state that: "The manner in which the draw is accomplished is, within limits, of equal, if not greater importance to the success of the operation than the physical properties of the steel itself." Montgomery⁷ points out that next to die design, lubrication is the greatest factor in producing good stampings. "Efficient lubrication of production operations will effect a greater net saving to the average stamping plant than any other single factor except die design and construction."

The actual strength of the sheet or strip for most forming and drawing jobs is comparatively low. Except in the harder tempers, where the carbon may be as high as 0.25%, the steel used for drawing jobs is S.A.E. 1010 analysis. Winlock and Kelley⁸ in regard to the strength of the material state: "Strength and rigidity are usually imparted to a stamping by designing it so that it will most effectively resist the forces imposed upon it in use by virtue of a high section modulus."

Aging is another factor influencing the drawing quality of sheets and strip. A material at the time of shipment may be perfectly suited for the job, but if it is not used within a reasonable time, and aging takes place, it is probable that increased breakage will result and surface disturbances will be present in the finished part.

The amount of aging depends on the analysis, method of manufacture of the steel, amount of skin rolling, time, temperature, and the original hardness range of the material. Whittemore⁹ using random samples over a long period of time, determined the average amount of aging in different hardness groups for different periods of time. The increase in Rockwell hardness was used as the measure of aging. On that basis he recommended that specifications make an allowance for aging.

After a material has aged to a certain extent it loses its ductility and if then worked or formed stretcher strains occur. Winlock and Laverne¹⁰ along with many others have studied "stretcher strains," "worms," or "lines of Luder." They found that this disturbance tends to occur in those parts subject to a deformation of 1.5-10% during forming. In tension the lines are low spots, in compression they are elevations. They attribute the stretcher strains to fluctuations at the yield point. Cold working by roller levelling or skin rolling generally eliminates the sharp yield point and the tendency to stretcher strain.

For a true picture of the conditions within a given sheet or strip, it is necessary to select samples with regard to the method of manufacture. In checking the analysis of strip or sheet which was "straight rolled" it is necessary to take millings from the entire cross section. If the amount of segregation is to be checked, samples should be taken from edge and center. If the sheet has been "cross rolled" from sheet bar the composite sample from end and center of the sheet will give an average analysis, and tests on the end and center of the sheet will give a check on the amount of segregation present. The same remarks are true for any test applied to sheet and strip; the samples should be taken so that the tests give a true picture of the whole strip or sheet. A certain amount of nonuniformity is to be expected. It is impossible to have identical properties in all parts of the sheet or strip especially when it is manufactured from rimming steel.

Inspection—There are certain defects which are more likely to occur on strip and sheets made by the continuous process, but there are certain defects found in sheet mill sheets that are absent on the strip product. The following is a partial list of the defects which may be found during inspection; some cause immediate rejection, others cause the material to be degraded into a lower class, or cause rejections, depending on the severity of the defect.

Annealing sticker	Grease pits	Pinchers
Bad steel	Guide scratch	Pipe
Black scratch	Handling scratch	Reel kink
Blisters	Heavy annealing border	Roll mark
Camber	Heavy to gage	Roll stop (for mill adjustment)
Chatter	Hickey	Rolled edge (guides too close)
Coil break	Hot mill scale	Scale pattern
Copper stain (pickling)	Laminations	Short
Corrugations	Light to gage	Side strains
Cutting machine scratch	Loose oxide	Slivers
Dimple (from annealing sticker)	Narrow	Strains
Dirt pits	Normalizer break	Stringer
Enter and end marks	Normalizer scale	Tandem mill scratch
Fluting	Not flat	Wavy
	Pickle house scratch	

Temper—The processing of cold rolled sheet and strip is varied to control the physical properties within the ranges found most suitable. This is done by controlling the amount of reduction, the annealing and the final amount of cold rolling after the anneal. These influencing factors are worked out in each plant according to their equipment and conditions so that the finished material will have the desired characteristics. The amount of cold work can vary from a pass through the roller leveler, which does not affect the thickness to any appreciable extent, or a pass on the skin mill with reductions up to a maximum of several per cent, to heavy cold

rolling which reduces the thickness as much as 50% or more. The increase in hardness over the annealed condition depends on the amount of cold work done after annealing, and the ductility falls off rapidly as the amount of cold work increases.

Table I gives the approximate physical properties of different tempers. The values also apply to sheets made by the cold strip process.

Table I

Approximate Physical Properties for Various Tempers of Cold Rolled Strip Steel*

(These values are given as information only and are not intended as criteria for acceptance or rejection.)

Grade or Temper	Rockwell Hardness B Scale, $\frac{1}{16}$ in. Ball	Depth of Cup for 0.050 in. Thickness of Strip, mm. ^a	Tensile Strength, ^b psi.	% Elong. in 2 in. for .050 in. Thickness of Strip ^c	Remarks
No. 1 Hard	90 \pm 6 ^d	6-7	80,000 \pm 12,000	3 \pm 2	Intended for flat blanking only
No. 2 Half Hard	80 \pm 5	7-8	64,000 \pm 8,000	9 \pm 5	Intended for easy bending up to 90° across the grain.* (No bending along the grain).
No. 3 Quarter Hard	69 \pm 5	8-9	54,000 \pm 6,000	20 \pm 7	For shallow drawing and stamping, where a very smooth surface is required. Bends 180° across the grain. Bends up to 90° along the grain.*
No. 4 Soft or Plushid	58 \pm 6	9-10½	48,000 \pm 5,000	30 \pm 6	For fairly deep drawing where no sign of surface strain is permissible. Bends 180° both ways of the grain.
No. 5 Dead Soft	45 \pm 7	10-10½ 10-11½	44,000 \pm 4,000	39 \pm 6	For deep drawing where slight stretcher strains are permissible. Also for drifting. (Erroneously called "extrusion.") Bends 180° both ways of the grain.

^aCup depth varies with thickness of strip. For grade No. 5, dead soft temper, the depth is given approximately by the formula $D = 10.5 \text{ mm.} + 6.4 \log "t"$ (t = thickness in mm.). Other tempers vary in a similar way.

^bTensile Properties are based on the standard tension test specimen for sheet metals, Fig. 7, A.S.T.M. Designation E 8, 1936 Book of A.S.T.M. Standards, Part I, p. 833.

^cElongation in 2 in. varies with the thickness of strip. For grade No. 5, dead soft temper, the percentage elongation = $41 + 10 \log "t"$ (t = thickness in mm.). Other tempers vary in a similar way.

^dFor cold strip .069 in. and thinner in thickness the Rockwell B hardness range is 96 \pm 6, with corresponding increase in tensile strength and drop in depth of cup test.

*To bend across the grain means that the crease formed by the bend shall be at right angles to the length of the cold rolling strip. To bend along the grain means that the crease formed by the bend shall be parallel with the length of the cold rolled strip.

*Tentative Specifications for Cold Rolled Strip A.S.T.M. Designation A 109-35 T.

The Tensile Test—Kenyon¹¹ points out that the "rate of strain" is the proper method of measuring the speed of testing, rather than the speed of the cross head of the testing machine. This permits a better correlation of the test data when comparing the results on samples of different gage lengths. Kenyon found that variation in the rate of strain from 0.08-0.38 in. per min. raises the yield point about 2500 psi., and lowers the per cent total elongation, both in 2 and 4 in., about 3%. Increased rate of strain also lowers the per cent "uniform" elongation. Although total elongation is the usual value recorded, the "uniform" elongation is truly characteristic of the material while the total elongation is not, due to the disturbing effect of the shape of the specimen. Kenyon suggests measuring this value on the "stress strain" curve as drawn with a 10 X extensometer. This measurement is made horizontally from the start of the curve, to where the load ceases to increase. The gage length is immaterial as far as the determination of this quality is concerned.

Kenyon and Burns¹² describe a new extensometer, wedge type, designed to draw accurate curves so that uniform and total elongation may be measured from the curve. Measurements of elongation may also be made in the area of the yield point phenomena. They describe test practice and a number of typical curves are reproduced. When due to cold work, the yield point becomes indefinite, it is considered to be the stress corresponding to an elongation increase of 0.5% of the gage length, determined by measurement from the stress strain curve. (On machines

not equipped with recording devices this point may be determined with any accurate extensometer.) The upper yield point is defined as the stress at which yielding begins; the lower yield point is the smallest value of stress to which the load sinks during stretching, or the smallest load under which stretching proceeds. A special celluloid scale, designed for measuring these values is described.

Two requirements for any test, according to Eksergian¹³ are: "(1) That the conditions of test duplicate those which actually exist—or that a relation between the two may be established, and (2) that the test contains sufficient information in a form which may be comprehensively interpreted. The simple tensile test, although somewhat lacking in the first requirement, fulfills the latter quite well. The general extension denotes the extent to which the material will behave uniformly while the local extension designates the ultimate capacity of the weakest section. These values should be considered with respect to the type of draw when correlating results."

Under definite testing conditions, the tensile test results are reproducible in any laboratory. The work of standardizing this test has covered a considerable period of time and many of the questionable points have been cleared up. For mill production testing of drawing quality material during processing and at the time of shipment, the tensile test is usually too time consuming. Consequently the simple tests, such as the Rockwell hardness and the Olsen or Erichsen cup draw tests, are used for this purpose. Mills are generally able to establish a correlation between the Rockwell and Olsen tests with actual performance records and feel that the two tests, properly considered are indicative of drawing quality, but are not a guarantee of performance because of the numerous drawing hazards external to steel quality. If a similar number of tensile tests were made, they would undoubtedly establish some relationship. The test is standard on plate and other materials having a strength requirement specification.

Hardness Testing—The useful hardness range on cold strip and sheets is roughly B-35 to B-100 Rockwell. When properly made, the Rockwell test on sheet and strip is consistent, reliable, and an effective measure of hardness. There are certain precautions necessary to obtain accurate results, and these are discussed in the article in this Handbook on the Rockwell Test.

Ductility Tests—The tests most commonly used to determine ductility are the Erichsen and Olsen cup tests, and to a certain extent, they give similar values. The Erichsen machine measures the gage and depth of cup in millimeters, while the Olsen test measures the same values in thousandths of an inch. The impression or draw of the Erichsen test is made with a cone shaped, spherical end plunger, while that of the Olsen test is made with a steel ball. It has been found by making a number of check tests that when the Erichsen result in millimeters is converted to inches, the actual value in thousandths is 10-14% higher than the Olsen test. Converting results on this basis will give comparative figures. However, this holds true for groups of samples, rather than for individual tests.

These two tests have never been standardized; consequently there is no generally accepted method of making either test, but the practice here described, if followed consistently, is probably as satisfactory as any. Briefly, cut the sample as wide as the machine will conveniently handle, oil the side in contact with the ball or plunger, tighten the die as snug as possible without jamming the screw, and then make the test. The "end point" of the Erichsen test is when, by observation, the break will just admit light; that of the Olsen test is when the needle of the pressure system begins to drop back. Variables in making the test are: Strip too narrow, giving high results; not breaking the cup, or breaking it too much; speed of testing; die tightness; lubrication and surface of sheet or strip. The most common error is to open the break too wide.

As these tests have never been standardized, there are many who doubt their actual value, while others believe that they are as good as any other test, provided a good practice is worked out and then adhered to rigidly.

Watson¹⁴ stated that a correlation between laboratory ductility tests and plant usage might be worked out in one plant, but the same correlation would not necessarily hold good for another plant.

Gillett's¹⁵ opinion is, that making tensile tests in both directions and measuring the elongation in several gage lengths is rather time-consuming, and for this reason the cupping tests such as are made on the Erichsen, Olsen, Guillery, and Wasau testers are generally used for ductility measurements, often with measurements of the load required. The cupping test has obvious advantages in that it tests the sheet in all directions, it gives a deformation somewhat analogous to that of deep stamping and does it without introducing press variables such as die clearance. Gil-

lett gives a number of references expressing different opinions of the reliability of cupping tests and the actual properties determined by them.

It may not be possible to get an extremely close agreement between individual machines on single sheet samples, but groups of samples average fairly close. There is a noticeable spread on individual results. However, results on the same machine, by the same operator or groups of operators, using the same practice, will be fairly consistent over a period of time.

The examination of the cup after the test is completed gives additional valuable information. The surface near the break gives an indication of the grain size; the position of the break gives an idea of the amount of cold work the material has received after the anneal; and the shape of the break indicates the thoroughness of the anneal and the directional properties present. The ratio of pressure at 0.250 in. draw and the maximum pressure during the test are also of some significance.

The bend test, as outlined in Table I, is useful on the harder tempers but is not of great value on the deep drawing grades. Some make a practice of opening the bend after the test has been made and examining the inside of the bend for additional information. Others have found the reverse bend test, made according to a definite practice, to be informative; the number of the reverse bends that the material will withstand before failure is considered an index of its ductility.

Microscopic Examination—The microstructure of the metal is most important in the deep and extra deep drawing grades. Usually the samples are taken parallel to the rolling direction but it is often desirable to examine the structure in both directions. The samples can be bolted together or mounted in bakelite, so that the cross section may be polished and examined. It is good practice to take all pictures at X100, X500, or X1000 so that the results may be compared from time to time.

The grain size of the material is controlled within close limits by controlling the processing. The grain size is important; for some work it must be fairly large, on other jobs it must be small or "in between." The permissible grain size depends somewhat on the type and depth of draw. The shape of the grains appears to be important, and the condition and distribution of the carbides should be observed and noted.

All steels have inclusions or sonims. Whether these are harmful or not depends on the number, size, type, and distribution in the material.

While there are limits to the desirable ranges of grain size, these limits are not clearly defined to the extent that these sizes apply to all jobs. What may be desirable in one case may not be good in another; but the requirements for any part have a certain degree of latitude. Usually the grain size will vary somewhat from surface to midthickness due to segregation. The degree depends on the severity of the segregation, and in well made steel this difference is negligible. On a straight rolled material there will be some difference in grain size from edge to center, and the same differences will be found from end to center on sheets cross rolled from sheet bars. Any irregularity in normalizing, and the usual temperature differences within the annealing box are reflected by slight differences in grain size. These are normal and expected differences which cannot be entirely eliminated, and affect the drawing quality only when they are severe and abnormally large.

Large variations in grain size within a given lot are detrimental as differences in the hardness and flow of the metal in the dies must be compensated for by changing the draw ring or hold down adjustment. The smaller grained material must be held more tightly to pull out the buckles or wrinkles, while the same adjustment would probably break a larger grained sheet or strip. For this reason, it is inadvisable to try to work both large and small grained materials with the same adjustment.

Heating Steel Bars for Forging*

General—The details to be observed in the practice of heating and forging steel depend to some extent on the type and size of forging, method of forging, composition of the steel, and the subsequent disposition of the forging. The following suggestions are based on normal good practice for the production of steel forgings from bars and billets, up to and including 4 in. sq. or in dia.

There are six major metallurgical factors which should be considered in the heating and forging of the steel. These factors are:

- (1) Rate of heating to forging temperature;
- (2) Overheating and burning of the steel;
- (3) Forging temperatures;
- (4) Decarburization of the surface;
- (5) Scaling;
- (6) Finishing forging temperature.

Rate of Heating to Forging Temperatures—The time of heating should be just sufficient to bring the center of the bar or billet to the forging temperature. In general, for plain carbon steel of 0.50% carbon and less, a minimum time of 5 min. per in. of dia. or thickness is sufficient for heating bars up to 3 in. Although this is common practice, some metallurgists consider a slower heating rate more desirable. Bars over 3 in. in dia. or thickness require a slower heating rate. For steels having higher carbon content than 0.50%, somewhat slower rates of heating should be used. With some steels, even preheating should be employed in order to avoid rupturing when forced heating is applied. It is advisable with larger sizes or irregular shapes to determine the heating rate by imbedded thermocouples for the particular furnace and bar to be forged. To utilize the minimum rate of heating, it is necessary that the bars in the heating furnace do not touch, and that the furnace is of sufficient capacity.

Overheating and Burning—Overheating may be produced in the forgings by heating to such a high forging temperature that the grains in the steel become excessively large. This large grain size results in impaired physical properties of the metal unless the grain is refined by proper mechanical or thermal treatment.

The term "burning" as applied to steel is somewhat misleading, because the chemical reaction of the steel with oxygen is not necessary to produce the so-called "burning." This is evident since steel may be burned entirely on the inside, but may appear quite satisfactory on the surface. Burning of steel entirely on the inside is usually due either to decarburization on the surface or to an inside temperature which is much hotter than the surface at the time of forging. However, the presence of turbulent, free oxygen in the atmosphere surrounding the steel will usually cause the steel to burn at a much lower temperature than when no free oxygen is present.

Burning is an extremely overheated condition which causes the more fusible constituents of the steel to melt and run out into the grain boundaries and leave voids between the grains. Burning may occur in the heating furnace before any forging is done on the steel.

Direct impingement of the flame against the steel, especially if of an oxidizing nature, is likely to produce spot burning or overheating, and should, therefore, be avoided. Likewise, impingement of a jet of air against the steel is to be avoided in the heating furnace. Air may be used to blow the scale off the steel during the forging operation, provided the forging temperature of 2400°F. is not exceeded.

Forging Temperature—The safe forging temperature to be employed for steels depends on the composition of the steel, the furnace atmosphere, the temperature measuring equipment, the furnace equipment, and the type of forging operation.

In general, for either plain carbon or alloy steels, the forging temperature is lowered as the carbon content of the steel is increased. The effect of the various alloying elements on the forging temperature must be considered in relation to the quantity used and the other elements combined with them.

The flow of steel or its plasticity at the forging temperature depends upon the composition of the steel and the forging temperature. The higher the forging

*This article was prepared by the Subcommittee on Forging. The membership of the subcommittee was as follows: W. E. Jominy, Chairman; H. M. Spears, and A. M. Steever.

temperature, the greater the plasticity with resultant lower operating costs, but the finishing temperature is then generally higher, producing coarser grains. With higher forging temperatures, the steel is heated closer to the overheating and burning range and, consequently, good furnace equipment and accurate temperature measuring devices are necessary to avoid the danger of burning.

If optical or radiation pyrometers are used, it should be remembered that smoke, the reflection of incandescent flames or furnace walls, the distance from the hot object, the presence of scale, and the lack of black body conditions appreciably affect the accuracy of the reading. It is possible to correct for lack of black body conditions and the presence of scale, but much smoke or reflection from flames may make the readings valueless. On the other hand, if conditions can be made ideal, very accurate readings are obtainable with the optical pyrometer. If platinum-rhodium thermocouples are used, care should be exercised to be certain that the temperature of the thermocouple corresponds to that of the steel. Frequent checks of the accuracy of the platinum thermocouple are necessary since the wire is very easily carburized by carbon gases and is often contaminated by iron and silicon.

Decarburization—Practically nothing is known about the rate of decarburization in different atmospheres at forging temperatures above 2000°F. It is probably safe to assume that increasing the heating time will increase the depth of decarburization. All precautions should be taken to avoid decarburization, so that the forgings can respond to heat treatment and thereby produce the physical properties expected.

Scaling—Scaling is the cause of more forging difficulties than is usually realized. Scale ruins most refractories; it is often hammered into the surface of the forging, causing machining difficulties and weak spots; and sometimes causes sticking in the forging dies. Scale represents an economic loss of metal and loss of time in removing it. It is desirable to have as little scale as possible, so a minimum time of heating should be employed. The presence of free oxygen in the furnace atmosphere causes a decided increase in scaling. If the presence of free oxygen in the furnace atmosphere is avoided, little is gained in reduction of scale by having more than a moderate excess of carbon monoxide. It has been found that in a gas fired furnace, using ordinary city gas, practically the same amount of scale is formed when the atmosphere contains 8.0% carbon monoxide as when 0.5% carbon monoxide is present, and that it is necessary to exceed 12% of carbon monoxide before a marked reduction in scaling is produced. This applies also to oil fired or butane fired furnaces, provided no free oxygen is present. The rate of scaling is also increased rapidly with an increase of heating temperature.

The Finishing Forging Temperature—In drop forge work, the finishing temperature is usually well above the critical range of the steel and practically no strength is imparted to the steel by the mechanical work of forging, although a certain amount of grain refinement results. In many drop forge operations, the finishing temperature is so high that large grains remain in the forging. Consequently, for best quality forgings, it is advisable to normalize in order to obtain a uniform, well refined grain structure. In addition, normalizing usually makes the steel more easily machinable, relieves the forging and cooling strains, and produces a more refined grain structure, especially if the finishing temperature was comparatively high. The normalizing temperature selected should be sufficiently above the critical range to completely eliminate any coarse structure that may be present.

Cooling After Forging—After the forging operation, it may be desirable because of the shape or composition of the steel (usually high carbon) to retard the cooling rate of the forgings. To retard the cooling, the forgings may be placed in a more or less protected enclosure, in ashes or lime, or they may be placed in a hot furnace.

Forging Furnace—Because of the greater ease of temperature control, better control of the induced air, better control of the time cycle for heating the bars or billets, and better fuel efficiency, a continuous type of forging furnace equipped with pyrometers is recommended wherever possible.

Care should be taken to avoid the accumulation of oxide slag on the floor of the furnace, since the presence of such slag causes pitting of the bars or billets which come in contact with it. In oil fired furnaces there is often an accumulation of coke at or near the burners, and occasionally other places. This coke or carbonaceous material, if not removed, may fall on the bars and billets, carburizing

them at the point of contact and causing hard spots, and sometimes causing melting and pitting.

Rate of Heating Carbon Steel Bars for Forging—Plain carbon steel of 0.50% carbon and less, in sizes up to 3 in. sq., may be heated at the maximum rate of 5 min. per in. of dia. or thickness. Although this is common practice, some metallurgists consider a slower rate more desirable. For steel having higher carbon content than 0.50%, somewhat slower rates of heating should be used in order to avoid rupturing from too rapid heating. The rate of heating to be used will depend on the size of the bar and its composition. In general, bars of 1% carbon and over and 1 in. in dia. or over should be preheated to 1300-1400°F. before placing in the forging furnace.

Forging Temperature—The following table gives the maximum temperatures recommended for forging plain carbon steels of the carbon contents listed:

Carbon Steels to be Forged % Carbon	Max. Forging Temp. °F.
0.10	2400
0.30	2350
0.50	2300
0.70	2225
0.90	2150
1.10	2075
1.50	1900

Heating Alloy Bars for Forging—This recommendation is to cover the heating of alloy steels having a carbon content up to 0.60% and a composition corresponding to any of the following S.A.E. series: S.A.E. 2300, 3100, 3200, 3300, 3400, 4100, 4600, 5100, and 6100.

Heating Rate—Bars or billets of 0.50% carbon or less may be heated at the maximum rate of 6 min. per in. dia. This applies to sections of 3 in. dia. or smaller. For larger bars or higher carbon content steels a slower rate of heating is recommended to avoid rupturing from too rapid heating.

Forging Temperature—The following table gives the maximum temperatures recommended for forging the above listed alloy steels of the carbon contents as indicated:

Carbon %	Max. Forging Temp., °F.	Carbon %	Max. Forging Temp., °F.
0.10	2350	0.40	2250
0.20	2300	0.50	2200
0.30	2250	0.60	2200

Precautions—In addition to the recommendations on pages 663-665 attention is called to the following precautions:

- (1) It is suggested that the finish forging temperature be not lower than 1800°F.
- (2) Scale is more adherent in the chromium and nickel containing steels and additional precautions to minimize the scale formation should be taken. This can be done by:
 - (a) Making sure that no free oxygen is present in the heating furnace atmosphere.
 - (b) Reducing the temperature at which forging is carried out.
 - (c) Preheating the bars to not over 1400°F. and permitting them to be at the high temperature for a minimum of time. This is usually done with the larger sections only.
- (3) With larger forgings, slow cooling from the forging heat is advisable to avoid internal ruptures. When the section of the forging exceeds 3 in. in dia. for more than 6 in. of length, cooling should be slower than natural air cooling.

Large Forgings

By John L. Cox*

General—The two main reasons for forging steel are to reduce the block of metal to approximately the dimensions of the finished article, and to complete the work of refining the coarse grain of the steel ingot, which for alpha steels was started by the high heat required for forging. Secondary objects of forging are so to orientate the unavoidable inclusions in the metal that they will have the minimum injurious effect, and to increase the physical properties of austenitic steels.

Both temperature and time are necessary for the first refining action. Ordinarily the initial heat should be as high as is prudent for the composition, and for alpha steels should be thoroughly soaked through the mass. Subsequent reheatings may be lower in temperature, but the steel should be thoroughly soaked. Austenitic steels are preferably soaked out at a moderate heat, brought quickly to the forging temperature throughout, and at once forged. In general, forging preferably should continue until the metal is too cool to permit ready grain growth, which in most cases is approximately when the surface of the forging shows polished die marks, or when breaking scale has ceased to form.

Ingot for Forging—Ingots must be of the proper chemical composition and should be of a dead-melted steel. They may be of any advantageous shape that will permit satisfactory solidification. For solid forgings it is highly important that the part of the ingot entering the forging be free from secondary, as well as primary shrinkage, especially when cuts occur across the ingot axis, as in crankshafts. In general this solidity can be obtained only by using ingots cast big end up and fed by a refractory-lined sink-head of ample proportions, unless very excessive top scrap is to be cut.

Complete freedom from central shrinkage is not so important in ingots for hollow forgings, especially in cases where the ingot is bored cold or trephined hot by a hollow punch, but it is always desirable.

The cross section of the ingot should be such as will permit finishing under proper conditions after heating, with a reasonable amount of reduction to insure thorough working throughout the section to be used so as to cause complete destruction of the ingot crystallization. Excessive reductions are not in themselves beneficial to good steel. They are injurious to pressure cylinders when forged solid and bored out, or even when forged hollow unless made by expansion of the diameter of a thicker walled cylinder, and may be expected to produce low extensions in tangential test bars taken in a transverse plane. The larger it is the more slowly an ingot cools; consequently, the coarser is its crystallization, the more pronounced the segregation, and the more serious the internal defects are likely to be. There is then little or nothing gained by giving more pronounced orientation to more numerous and larger inclusions, or by putting more work into breaking up a worse initial structure, with always the risk of the defects remaining.

Excluding forgings with large collars, a reduction of 3:1 should answer for nearly all work stressed and tested longitudinally, while a reduction of 2:1 should suffice for hollow work stressed and tested transversely.

For forgings with large collars there must be greater dependence on the heat refinement, but a reduction of about 1½:1 should be allowed on the collars. It is bad practice to round up an ingot that will barely yield the collar diameter.

To avoid excessive liquation and the coarse crystallization of slow cooling, it is advisable that ingots for forgings be cast in iron molds with heavy chill walls. Further, the metal cooling in basaltic columns from chill mold walls is cleaner and stronger than the interior metal of miscellaneous crystals. Wherever possible, such metal should be conserved for the more highly stressed parts of the forging. If of a size and of a composition making the step safe, an ingot may be allowed to go cold after casting. Conditions will dictate whether cooling be freely or at a restricted rate, or only after annealing. If very large, it is preferable to charge the ingot into the forge furnace while still hot, to avoid waste of heat and the risks of cracking during cooling and reheating.

Heating—Heating should be done with a soft, noncutting flame to avoid excessive loss by scaling and the risk of burning the metal. Ample time must be allowed

*Chief Engineer, The Midvale Co., Nicetown, Philadelphia.

for bringing the ingot to forging temperature if internal fire-cracks or "clinks" are to be avoided, which are formed when the nonplastic center of the ingot is ruptured transversely by the pull of the expanded surface metal. The time to heat is an increasing function of the size of the ingot, depending, too, upon its initial temperature.

When plain, medium carbon steel ingots of 40 in. in dia. are charged cold, safe practice represents heating about 1 hr. to the in., with a soaking time of $\frac{1}{4}$ hr. to the in. after reaching heat. Alloy steels have much lower coefficients of conductivity, so require proportionately longer time to heat.

For best physical results ingots of austenitic steels should be thoroughly soaked at approximately 1700°F., brought quickly to the forging temperature throughout, and forged without the usual soaking. However, the surfaces are likely to be torn. Better surfaces and more plastic material for forging will follow a heating more nearly of the type usual for alpha steels.

Forging—The forging tool may be a steam hammer or a hydraulic press, with sufficient power to work the metal thoroughly. The slow movement of a press tends to work large masses more deeply, and although the maximum pressure is limited it can be exerted at any point of the stroke. There is no theoretical limit to the pressure produced by a hammer, but the power of the tool decreases rapidly with restriction of the stroke and must be proportional to the work if more is to be done than move the surface metal. Forging should start by comparatively slight reductions on every face to consolidate the ingot structure, followed by the heavy reductions of the main roughing step. The preliminary consolidation is of especial use before spreading an ingot lengthwise of the dies, as it tends to prevent tears in the surface.

The metal must be worked throughout to weld any clean-walled internal openings that may exist and to refine the grain, as well as to avoid transverse fracture of the center, and to avoid mechanical piping of the bottom of the ingot by drawing the surface metal over the end. Enough reduction should be left for the finishing step to insure work being continued until the piece has fallen to a temperature too low for any considerable grain growth to occur.

Since the orientation of inclusions profoundly affects the stretch and contraction of the steel in which they occur, it is important to cause flow of the metal in the direction of the stresses to be borne. For this reason upsetting, or expanding on the horn or expanding mandrel, at some step in the forging operation greatly improves transverse tests.

When making set-downs with V tools, care must be exercised that the tools be not sunk too deeply to allow good reduction by forging below the bottom of the cut, either by radius tools or the rounded edge of the die, for the V tool cuts and stretches but does not forge. A V tool sunk deeply in metal not quite hot is very apt to produce a cavity in the metal below it.

It is important that sufficient metal be left between set-downs, especially in the case of collared shafts, to produce the intermediate final length required with a minimum cut on the inner faces of the collars. Excess metal may be turned off the shaft, but shortage of metal requiring part of the collar to be turned to the shaft diameter is very bad practice, as it puts into the highly stressed part of the shaft metal which has had only the reduction of the slightly stressed collar.

Long forgings of large diameter or of sensitive composition must often be kept hot (by auxiliary heating means outside the forge furnace) throughout those finished portions which would otherwise cool too quickly.

Sufficient top scrap must be cut to remove all trace of central ingot shrinkage that would be injurious in the finished article, and as much more as the specifications require. Sufficient bottom scrap should be cut to remove all casting surface defects, and if transverse tests be required from an unexpanded forging it is wise to cut considerably more.

Annealing—Except for the softest materials, carefully finished, it is of advantage—and in the case of solid forgings of large dimensions or forgings of high carbon or hardenable alloy steels it may be imperative—to anneal or otherwise slowly cool after forging is completed. It is well to check cooling before the temperature has reached about 600°F. if flakes and internal or external cracks are surely to be avoided.

If only part of a sensitive ingot has been used and the balance is to be reserved for future use it should be annealed, or buried in ashes, to avoid cracking.

If a large forging has only been buried in ashes from the forge, it must be regularly annealed to free it from stresses and refine its grain.

Annealing substitutes the grain size of its temperature and time for that existing in the piece as it left the die. If finishing be done at a high temperature it will require a higher heat to refine the existing grain than if the finishing had been done at a more suitable heat, and the resulting structure may require one or more further annealings at successively lower temperatures to produce the best annealed structure of which the piece is capable. Very large pieces often require the repetition of a particular annealing step before the full effects of its temperature have been obtained. This is better practice than to lengthen unduly the time at that temperature.

Forgings of austenitic steel, being always in the original phase with no volume changes occurring at passage through a critical temperature, are comparatively free from stresses and strains. They need only be heated sufficiently to relieve the stresses due to unequal rates of cooling.

Treatment—When higher physical properties are required than are obtainable from a forging in the annealed state an increase may usually be obtained by normalizing, or by quenching and tempering.

Normalizing consists in heating the piece to a temperature somewhat above that at which the metal is in the gamma phase, holding it there for a time sufficient for homogenization to occur and then cooling it freely in the open air. Depending upon the size, character and chemical composition of a forging, this step may not, or should, be followed by a tempering at a heat well below the critical range. The result is usually a moderate increase in tensile strength, a considerable increase in elastic limit, with a small loss in ductility.

When still higher properties are required and the character of the forging permits it, the highest attainable figures are reached by a heating such as described for normalizing, followed by a quench in a liquid medium, usually oil or water, followed by the tempering.

It is usually considered unsafe to apply this drastic treatment to solid forgings of any considerable diameter; it is rarely given to pieces over about 8 or 10 in. diameter or having walls over 8 in. in thickness, but under proper conditions it can be used on those much larger.

Austenitic steel forgings in general can only be softened by heat treatment. Balanced high physical properties must be obtained by work done cold or at comparatively low temperatures; for while some increase in tensile strength can often be gained by reheating forgings, with carbides in solution, to a temperature at which the carbides will precipitate, there is usually a disproportionate increase in brittleness and a probable loss in corrosion resistance.

Internal Inspection—Exposed defects on the surface of a forging are easily examined and their seriousness evaluated, but hidden defects may be as serious as unexpected. For this reason, it is always advisable to bore an axial hole through every major forging when such a step is possible. The hole should be as large as the necessary residual strength of the forging will permit. The larger the ingot from which the forging was taken the larger, if possible, should be the axial hole. Such a hole permits an examination of the interior of the forging by means of a bore searcher and will disclose the presence of shrinkage cavities and transverse fissures the existence of which otherwise would be wholly unsuspected. Slight defects, if present, may frequently be ground or machined out without undue loss of strength, but transverse cracks are sufficient cause for condemnation.

Not only does this axial exploration hole allow closer inspection, but it helps to reduce the stresses imposed both in heating for treatment and the subsequent cooling. Its importance is greatest when a liquid quenching step is involved, and it is practically indispensable in the quenching of large forgings, by allowing access of the cooling medium to the interior of the piece.

In all cases sharp re-entrant angles in any of the steps of manufacture or on the finished product should be avoided, as they form starting points for failure in treatment and service. The most liberal fillets compatible with the design should be allowed. Too small fillets may be a source of trouble in manufacturing operations as well as in service.

Fabricating and Finishing the Stainless Steels

By V. W. Whitmer*

The forging operations are not covered in this article as they are discussed in the article on the Forging of Stainless Steels on page 841 of this Handbook.

Types—The use of stainless steels in various industries is today quite large and varied. There are many types available to meet specific conditions insofar as analysis is concerned, but nearly all of them can be grouped in two general classes, from a fabricating standpoint. The first class, containing chromium as an alloying element, with varying amounts of carbon for heat treating purposes, is generally known as the straight chromium or ferritic type. The second class, containing both chromium and nickel, with low carbon, does not respond to heat treating for hardening. It is known as the chromium-nickel or austenitic group.

Excluding the higher carbon alloys in the straight chromium group, the two most commonly used alloys in these groups are probably those containing 18% chromium with low carbon, and the 18% chromium and 8% nickel. In both groups there are numerous others containing higher percentages of alloying elements, chiefly for heat resistance, but they are worked much the same as these two. Hence, in this article only the two alloys mentioned will be considered with additional notes when necessary.

Hot Working Operations

Piercing 18% Chromium Steel—For piercing, heat the same as for forging. A higher temperature will generally prove satisfactory. While the 18% chromium has been the most commonly used in the group the higher chromiums of 23 and 28% have been pierced successfully.

Piercing 18-8 Alloys—For piercing heat the same as for forging the 18-8 alloy, but to a higher temperature. The 18-8 alloy is the most commonly used in the chromium-nickel group. The higher alloys such as 25-12 and 25-20 have also been pierced successfully, the latter offering considerable difficulty.

Welding 18% Chromium Stainless—This alloy can be welded by any commercial method except forge or fire welding. Tight, solid welds are produced, insofar as fusion and porosity are concerned. A base wire of the same analysis as the steel is used with a slightly reducing flame for gas welding. For arc welding use a coated electrode which will protect the metal going through the arc from oxidation by the air. It will also cover the deposited bead with a slag blanket which stays molten to prevent loss of any chromium by oxidation. Because of the high temperature employed in welding a large grain will be developed, resulting in a brittle weld. At elevated temperatures such as 400°F. and higher some toughness is present. However, the 18% chromium is not recommended for welding, because it does not respond satisfactorily to subsequent heat treatment. If the chromium should be 15-16%, it is possible to anneal after welding and produce good ductility and bending properties.

The higher chromiums behave in a similar manner, but the lower type, around 12% chromium, is capable of heat treatment and can be annealed to show some ductility after welding. Recent work has shown that additions of columbium, titanium or aluminum will reduce air hardening in the 12% chromium alloys. Such additions to the electrodes do not produce soft ductile weld metal and hence, if the welds are to be placed in service as welded—an austenitic electrode such as 18-8, 25-12 or 25-20 should be used, depending upon the application. Such welds will be tough and ductile but will have a higher coefficient of expansion on heating and cooling than the straight chromium alloy. Nevertheless, welding is not frequently employed on these alloys.

Welding 18-8 Alloys—The chromium-nickel stainless steels are well adapted to welding and like the others can be welded by any commercial method except fire. Fire welding is not successful, as a refractory film of oxide forms on the surface of the material at the welding heat which will not dissolve or fuse with the commercial fluxes used today. This film acts as a separator, when the pressure is applied on the two sections, and prevents adhesion.

*Metallurgist, Central Alloy District, Republic Steel Corp., Massillon, Ohio.

In gas welding a rod of the same composition should be used with a slightly reducing flame, having about $1/32$ in. of acetylene feather on the end of the inner blue cone to prevent any possible oxidation of the chromium. If more acetylene is used the weld may become carburized, and with less the chromium may be burnt out. It is also advisable to apply a water paste of a good stainless flux to the bottom side of the joint to protect this side from contact with the air.

The 18-8 alloy has a high coefficient of expansion, about 60% more than common steel, and it is therefore necessary to hold the work in some manner while welding to prevent the edges from moving away from each other. Because of the greater expansion, the joint should be so held as to produce as little buckling as possible when cooling. Gas welding is used chiefly on 16 gage and lighter sections, although it can be satisfactorily used on heavier sheets.

Electric arc welding is probably the most common method used on stainless steel. A heavy flux coated electrode of the same analysis is necessary. This flux protects the molten metal, both while going through the arc and after being deposited, from oxidation by the air. It should not contain any material which would raise the carbon content of the weld metal, as this would reduce the ductility as well as the corrosion resistance. Use reverse polarity, that is, the electrode is positive and the work is negative. The 18-8 alloy has a lower melting point than steel, as well as a lower heat conductivity; therefore, less heat can be used and good penetration will be obtained in comparison with mild steel. A heavy bead or series of heavy beads should not be deposited at one time, as the excessive contraction will cause cracks. Deposit light beads about $1/8$ in. or less in thickness. All 18-8 welds properly made will bend flat back on themselves in either direction on $1/8$ in. plate without cracking.

Occasionally, columbium or titanium additions are made to 18-8 S to prevent carbide precipitation. This is not necessary with low carbon in light plates but is desirable in thickness over $1/2$ in. or where the equipment will operate in the carbide precipitation range of 1000-1500°F. and under corrosive influences. Titanium, in the welding electrode, is not advantageous, as it is nearly all lost during welding. Columbium is more efficient and will be reduced to a less extent.

Spot, seam, and flash welding are satisfactory on 18-8, but because of the characteristics of the alloy a closer adjustment between current time and upset are important. Automatic control is highly advisable with these products. Less total heat will be required than with the same sections of common steel.

The same procedure as with 18-8 should be employed in welding the higher chromium-nickel alloys. As these alloys are usually subjected to high temperatures, the weld metal as well as the plate or body must withstand the same service.

Cold Forming Operations

Cold Rolling 18% Chromium Stainless—The straight chromium alloys can be cold rolled in sheet or strip or drawn into wire similar to steel, except that lighter drafts, less speed, and greater pressure are required. High finish surfaces can be obtained on cold rolled strip. Very little polishing is required on an article made from this product. The hardness on cold working will increase to about 187-241 Brinell (95-100 Rockwell B) but will seldom exceed this range. Annealing will reduce these values to about 140-160 Brinell (80-85 Rockwell B).

Cold Rolling 18-8 Stainless—The chromium-nickel alloys can be cold rolled into strip or drawn into wire by methods similar to those employed for the straight chromiums, and will yield high finished surfaces, but considerable hardening will result. Cold working will raise the hardness up to about 400 Brinell (40-44 Rockwell C), with as high as 250,000-300,000 lb. tensile strength.

Drawing 18% Chromium Stainless—This alloy has about two-thirds as much ductility as ordinary deep drawing steel. In stamping, the draw should therefore be generally less for each operation. It is frequently possible to take two or more reductions without annealing under certain conditions, although, it is generally advisable to anneal after each operation. Annealing should be done at 1450°F., followed by air cooling. A good drawing lubricant is necessary in order to adhere to the work in the presence of greater pressure than required for ordinary steel. Good adhesion and lubrication should be stressed rather than a heavy base. In the straight chromium group, the alloys containing over 23% chromium will not be as good from a drawing standpoint as the lower ranges.

Drawing 18-8 Stainless—Because of its high ductility, this alloy is extensively used in deep drawing work. It has a much higher elongation as measured by a tensile test than extra deep drawing steel, showing about 45-50% as compared to 25-30% elongation in 8 in. for steel. Likewise the Olsen and Erichsen test values are higher. It is subject, however, to rapid hardening on cold working; hence as much work as possible should be performed in one operation. It is difficult to produce deep draws without annealing between operations, although two light draws can frequently be made without annealing. This annealing consists of cooling rapidly from 1950°F. either in air or water.

Reduction of 30-35% can be made in the first operation, but subsequent reductions should be about 20%. If too much work is done at one time and the article permitted to stand too long before annealing, it is apt to crack from excessive cold work. For this reason, if more than 40% reduction is made the job should be annealed at once. The presence of a flange will reduce this tendency considerably. About 2-2½ times as much clearance should be allowed as for steel or brass.

Because of the high physical properties and stiffness of the 18-8 alloy, one-third more power will be required to produce a given draw. A lubricant with high adhesive qualities capable of withstanding the high pressure without squeezing is quite necessary. All lubricants should be completely removed before annealing, as it will very likely injure the metal surface if left on during the annealing operation. The dies, for production work, should be hard, bronze inserts for the rings and either bronze, steel or cast iron for the punch. The ring should be kept well polished, if possible, in the direction of drawing. Proper choice of lubricant should assist in maintaining this polish to reduce scoring.

Spinning 18% Chromium Stainless—The straight chromium alloys, especially in high ranges of 17% chromium and over, have not been particularly successful in spinning operations. Reductions are less and more annealing is required than with the lower alloys. For best results with this type, the chromium should be about 12.0-17.0%.

Spinning 18-8 Stainless—The alloy 18-8 of spinning quality, having a high ductility in the annealed state is well adapted to spinning. Many articles have been spun from 18-8 where the number required or the variety of size and shape did not warrant making up dies for deep drawing.

In such cases, 18-8 can be spun, but it may be necessary to anneal, as required at certain stages. The ordinary tools or the roller type can be used. A chromium-nickel cast iron or oil hardened steel roller works well because of its ability to hold the lubricant. A heavy body grease or soap must be employed, keeping the surface well covered to prevent scoring or abrading. Do not attempt to do too much work before annealing, as cracks are apt to develop. Maintaining a flange while spinning has been found to be of value in reducing breakage.

Soldering 18 and 18-8 Chromium Steels—Both types of stainless steels are soldered readily, as the analysis has no bearing on the strength of the finished joint. If pickled sheets are employed, the ordinary zinc chloride or cut acid with commercial half and half solder will give fair results. However, stronger joints will be produced if the special stainless steel soldering fluxes are used, several of which are on the market. If the steel is polished, the edges should be roughened with a coarse file or emery cloth to obtain adhesion. Use a large soldering iron with as low a temperature as possible to keep buckling to a minimum. When the joint is completed it should be washed with about a 5% soda solution. Washing will neutralize any remaining acid which, if not removed, will corrode the metal. If the joint is of such a nature that washing on both sides is impossible, it should first be tinned with a strong flux and washed, then assembled and finish soldered with a flux that is as near neutral as possible, so that if it is not removed, it will not seriously corrode.

Machining 18% Chromium Stainless—This alloy machines a little differently than ordinary steel and more nearly resembles a 0.40-0.50 carbon steel. For best results it should be in the cold drawn or cold drawn and annealed condition. The same applies to sheet or strip either cold rolled and annealed or just annealed.

The 12% chromium containing higher sulphur along with various other elements is recommended for machine work. On a basis of 100% for screw stock the product will rate about 90% or better. It is used on automatic screw machines along with regular screw stock.

Machining 18-8 Stainless—This product is tough and difficult to machine. Best results are obtained with a slow cutting speed and moderately heavy cuts. Tools must be kept sharp and cutting, as any dragging will tend to work harden the product and will further increase the difficulty. Drills should be ground flatter than usual to produce less wedge effect and the speed reduced to about one-half that used for drilling steel. Center punch marks should be as small as possible to reduce the effect of cold working.

For drilling or cutting a good grade of sulphur base oil should be used. In sawing, a high speed blade should be used of the fine tooth, wavy type. A circular saw is preferred whenever possible.

Selenium additions to 18-8 will sharply increase its machining properties, but at the sacrifice of some corrosion resistance. This is generally not serious and the greater ease of machining more than warrants the slight loss in corrosion properties.

Pickling—Both the chromium and the chromium-nickel groups form an oxide when annealed in a reducing atmosphere which is practically impossible to remove by pickling. When a neutral condition is maintained, the sheet can be pickled in a solution of 10% (by weight) muriatic acid, that is, half and half commercial acid at about 130-150°F. or a mixture of 6-8% sulphuric acid with 2-4% muriatic at 150-170°F. The former is preferred, but is more expensive. After about 20 min. in this solution the section should be removed, dipped in cold water before any acid dries, then scrubbed and immersed in a 20% solution of nitric acid, either warm or cold. This operation will produce a clean white sheet which should then be washed in water and dried.

Polishing and Buffing—Both types of stainless steel if only rough ground with a coarse wheel, will discolor if subjected to a salt spray. However, if a higher finish is applied, no rusting will occur on the 18% or higher chromium steels or on any of the chromium-nickel steels.

Rough grinding should be done with 80 grit, set up with glue and abrasive on a cotton wheel. This should be followed by 100 grit with the wheel surface greased, then with successive fine wheels, such as 120, 150, 180, 200, and 240, depending upon the finish desired. Grit up to 180 should be of the manufactured type, low in iron. From 180 up, Turkish emery will give best results, as fewer deep lines will be produced.

For a higher finish, go through the 240 grit with grease, then buff with a stainless steel buffing compound on a cotton buff and follow with a few passes using green chromium oxide grease stick for final color. Do not buff with chromium oxide, as drag pits are likely to develop.

For cutting, a speed of 5,000-6,000 f.p.m. should be used and for buffing 6,000-8,000 f.p.m.

The Forging of Stainless Steel

By Owen K. Parmiter*

General Instructions—The term "stainless steel" may refer to any one of 60 or more corrosion resistant steel compositions, each one possessing some special property or particular characteristic not found in the others. All stainless steels, however, have some properties in common which include "red hardness" or resistance to the softening effect of heat and a low degree of heat conductivity. These characteristics make forging somewhat difficult. Careful preheating and prolonged soaking are necessary in all cases and some special compositions require extremely narrow heating ranges.

Since it is impractical to outline specific forging instructions for each type of stainless steel, in this article, the field has been divided into three general groups to include, The Hardenable Types, The Chromium Irons, and The Austenitic Types. Only the most popular and representative steels in each general group are considered.

Hardenable Types (Semi-martensitic and martensitic chromium-iron steels)—The various compositions included in this group possess air hardening properties and also red hardness to a limited degree. This makes forging somewhat difficult because rather narrow heating ranges are necessary. For all forging operations, it is necessary to preheat the stock and soak for a considerable length of time in the vicinity of 1450°F., also to hold longer at the required heat than ordinary steel. Frequent reheating is advisable. After forging, these steels should be cooled slowly and evenly; then they are hard and must be annealed if machine work should be required.

In forging the higher carbon types of stainless steel (above 0.60% carbon), care must be taken not to overheat them, for as the carbon content increases, the initial forging temperature decreases. The structure of these steels has a tendency to become austenitic if overheated, and when such a condition is present, the steel does not respond well to hardening.

Forging temperature ranges for this group are as follows:

Type No.	Commonly known as	Typical Carbon	Composition, % Chromium	—Forging Temperatures—	
				Initial Heat, °F.	Finishing Heat, °F.
501	5% Chromium Iron (46)	0.10	5.00	1950-2000	1650-1700
403	Turbine Blading Type	0.12 Max	12.25	2000-2100	1450-1500
410	Chrome Iron	0.12 Max	13.50	2000-2100	1600-1700
416*	Free Machining Type	0.12 Max	13.00	2100-2200	1500-1600
420	Original Cutlery Type	0.35	13.00	1950-2050	1650-1700
440	Surgical Instrument Type	0.65	16.50	1950-2000	1700-1750
440	High Carbon Cutlery Type	0.85	17.00	1900-2000	1700-1750
440	Ball Bearing Type	1.05	18.00	1850-1950	1700-1750

*Free Machining—contains high sulphur or selenium.

Soft Types (Semi-ferritic and ferritic chromium-iron steels)—The nonhardening steels comprising this group are highly malleable and ductile. For all forging operations it is necessary to preheat the stock and thoroughly soak at about 1450°F. Forging should be fairly rapid at the initial temperature but should be more gradual as the metal cools. Unless there is considerable reduction to be done, the temperature should be held as low as is consistent with workability, and in no case should the finishing temperature exceed 1400°F. If these steels are overheated, a coarse structure results and much of their toughness and ductility is sacrificed. Good refinement of grain is possible by finishing at a low heat. Although they possess virtually no hardening properties, it is sometimes desirable to anneal after low temperature working to remove strains.

Forging temperature ranges are as follows:

*Metallurgical Eng., Firth-Sterling Co., McKeesport, Pa. Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steevey, Chairman, R. W. Thompson, F. B. Foley, O. W. Ellis, H. M. Spears, W. E. Jominy, W. W. Orley, and J. H. Friedman.

Type No.	Commonly known as	Typical Carbon	Composition, % Chromium	Forging Temperatures	
				Initial Heat, °F.	Finishing Heat, °F.
430	17% Chrome Iron	0.12 Max.	14.00-18.00	1900-2000	1350-1400
430F*	17% Chrome Iron Free Mach.	0.12 Max.	14.00-18.00	2000-2100	1350-1400
442	20% Chrome Iron	0.35 Max.	18.00-23.00	1900-2000	1300-1400
444	28% Chrome Iron	0.35 Max.	23.00-30.00	1900-2000	1300-1400

*Free machining—contains high sulphur or selenium.

Nonhardenable Types (Austenitic chromium-nickel-iron alloys)—The steels in this group possess varying degrees of strength and hardness at the high temperatures necessary for forging. All of them are more difficult to forge than ordinary steels and require more blows under the hammer to accomplish the same degree of reduction. Like all high chromium steels, their heat conductivity is low so it is necessary to soak them thoroughly at the preheating temperature of about 1500°F. The first hammer blows should be light. With the exceptions of Type 310 and Type 311 none of these austenitic stainless steels should be held for a prolonged period of time at the initial heat of forging. All of this group of steels should be finished at a comparatively high heat (1700-1800°F). At forging heats lower than about 1700°F, these steels are hardened by the comparatively cold working and have a tendency toward red shortness.

Specification for this grade of stainless steel formerly called for 0.20-0.70% manganese. Recent experience has shown better hot working properties when the manganese content is between 1.25 and 2%. This is particularly true in the austenitic stainless steels containing molybdenum, columbium, silicon, and titanium.

Forging temperature ranges are as follows:

Type No.	Commonly Known As	Typical Compositions, %				Forging Temperatures	
		Carbon	Chromium	Nickel	Other Alloys	Initial Heat, °F.	Finishing Heat, °F.

Hot Mechanical Working of Steel*

Purpose of Hot Mechanical Working—Steel which is cast from the melting furnace into ingot molds must be reduced from the ingot by mechanical force through the intermediate stages of bloom and billet to bar, sheet, strip, coil, or forging, which are the common hot finished forms of steel. This mechanical force is applied to the steel while hot for several essential reasons.

The ingots into which the steel is cast from the melting furnace usually represent a considerable mass of metal which is slow to solidify and cool to room temperature; hence it has a very coarse crystalline structure. Material in this condition is deficient in ductility and very heavily strained. These strains are of sufficient magnitude to cause rupture of the mass if subjected to unequal or sudden temperature changes. To refine this structure is then one of the primary reasons for hot mechanical working of steel. By heating steel to its plastic state and mechanically working it, the coarse crystals of the cast ingot are rearranged, and the metal flows along desired lines. This results in a reduced section of greater homogeneity and refined crystal structure. By the proper selection of temperature and the application of mechanical work through rolls, dies, and the like, the physical properties of the forged steel may be increased over those of the original cast ingot both statically and dynamically.

Hot Working Range and Effects—Heating steel above a certain blue heat range of about 700°F. constantly decreases the strength and increases the plasticity until a temperature is reached where the lowest melting constituent of the steel starts to melt. At this particular temperature the strength is greatly decreased and the mass also loses plasticity and tends to crumble under applied stress. When this point is reached, mechanical work cannot be performed as the steel will crumble rather than flow.

The optimum hot working temperature is, therefore, a balance or average between decreasing strength and increasing plasticity. This temperature will vary with different compositions of steel and is covered by a range called the hot working range. The top of the range is limited by a margin of safety below the melting point of the lowest melting constituent, and the lower end by the temperature at which strength increases and plasticity decreases to the extent that excessive pressures are required to cause flow, thus limiting the efficiency of the process and possibly causing ruptures in the metal.

Finishing Temperatures—Although the final properties of the finished steel are usually determined by heat treatments applied subsequent to the hot mechanical working, the temperature at which the mechanical work is finished (so-called finishing temperature) is important in governing the final treatments necessary and the properties obtained. It is generally conceded that the lower the finishing temperature, the finer the structure of the mechanically worked piece and the more amenable it will be to simple heat treatments. The actual temperature is, however, limited by mass, shape, process, and other considerations. A special application of this principle is illustrated by the austenitic steels, wherein certain desirable physical properties can be obtained only by closely controlled finishing temperatures. Large forgings, and intricate shapes to be flowed into dies require relatively high finishing temperatures, and the required refinements of structure must be taken care of by subsequent heat treatment. With small and simple pieces, the finishing temperatures can be at or near the lower critical point, which produces refined structures that respond readily to simple heat treatment. A good example of the latter is the Damascus swords, which received repeated light workings at the critical and subcritical temperatures. The extremely refined structure thus produced responded to subsequent hardening, and a blade of remarkable properties was obtained.

Ingot Structure—The ingot of cast steel is made up of a mass of grains of varying sizes. The central portions of these grains are comparatively pure iron or ferrite, whereas the portions near the grain boundaries are correspondingly higher in the alloying elements and impurities. The resultant chemical heterogeneity is not entirely destroyed by diffusion or forging. Mechanical hot working causes

*Prepared by the Subcommittee on the Hot Mechanical Working of Steel. The membership of the subcommittee was as follows: S. C. Spalding, Chairman; J. P. Fleming, A. O. Schaefer, and W. R. Shimer.

these nonhomogeneous grains to be elongated in the direction of the working. Macroetching of a section parallel to the direction of working shows laminations or lines resulting from the chemical heterogeneity. Such lines are known as "flow lines" because they indicate the direction in which the metal "flowed" or was worked.

The physical properties of steel may differ markedly, especially in ductility and resistance to shock, in a direction parallel to these flow lines and perpendicular to them, particularly if the metal is not clean. Consideration must be given in forging practice to the service to which the forging is to be put. An example of this is the forging of rings. If rings are forged from a slab produced by elongating the ingot into a long block of rectangular section and subsequently trimming it to shape, certain sections of the rings will show radial flow lines and will probably have less ductility than the portions 90° away, which have tangential flow lines. For this reason, rings and forgings subject in service to tangential stresses are best upset or expanded in such a direction as to increase the physical properties in the desired way.

Mechanism of Hot Mechanical Working—The actual mechanism of the hot mechanical working of steel is divided into two classifications: Rolling and forging. The subdivision is by method of application of mechanical force. Rolling, as the term implies, works the metal by rolls; forging works metal by means of hammers, presses, and forging machines.

Fig. 1—Action of rolling.

Hot Rolling—Hot rolling is a mechanical method of hot working metal by causing the metal while hot to be fed between two rolls rotating in opposite directions. Hot rolling accomplishes three main purposes: First, reduction of cross sectional area; second, refinement of structure; and third, shaping of the metal into desired forms such as bars, sheets, rails, angles, and I-beams. The flow of metal in the rolling operation is continuous and almost entirely in a longitudinal direction (Fig. 1).

Blooming Mill—The rolling mill in which the first hot mechanical working of the cast ingot is done is known as the "bloomer" or "blooming mill." The function of the bloomer is to take the hot ingot as received from the soaking pit and break it down or reduce it to smaller size called a bloom or billet. This bloom is a semifinished product to be subsequently rolled on a billet mill or finishing mill, or used for forgings. The sizes of the majority of blooming mills range from 28-54 inches. The size is based on the distance from center to center of the pinions. Most bloomers are of the two high reversing type, which consists of two rolls mounted one above the other and reversible in the direction of rotation to allow for the passage of the metal back and forth through the rolls. Grooves or passes are cut in the rolls of a size and shape to accommodate the ingot and the various reductions desired. The usual procedure is a flat center pass called a "bull-head," used for breaking down the ingot to the size of the first pass, which is usually 13-14 in. wide. In addition, the blooming rolls contain several small passes, usually 8, 6, or 4 in. wide, depending on the finished bloom sizes required.

Operations on Blooming Mill—For an example, in rolling a 24 in. corrugated ingot to a 4x4 in. bloom on a reversing bloomer, the following method (which is for alloy steels and requires about 27 passes) is used:

The ingot is broken down under the bullhead (to 18x13 in.) by giving light drafts and turning each pass for the first four passes; it is then given 2 passes each way while being slabbled to 18x13 in. It is then turned and entered into the 14 in. pass, given 2 passes and turned; then 2 passes to 14x8 in.; turned and entered the 8 in. pass, given 1 pass and turned; then 1 pass to 5x8 in.; turned and entered into the 6 in. pass to 6x6 in.; turned and given 1 pass to 6x4 in.; then turned and entered into the 4 in. pass, and finished to a 4x4 in. bloom.

Billet Mill—In order to produce the size of billet necessary for use in the smaller finishing mills, it is customary to reroll the blooms, either with or without reheating.

ing, in some type of billet mill. The billet mill may be of the 3 high type, or may be continuous.

Finishing Mill—The billets or blooms, if not used for forging purposes, are rolled on smaller mills into bars of varying shapes and sizes. They may be rounds, hexagons, flats, or special shapes. Round bars generally are rolled in open pass rolls. Fig. 2 shows the passes and reduction of a 4x4 in. billet to a $\frac{3}{4}$ in. round. For special steels, more passes may be required, and the shape of the passes may not be the same as shown.

Flat bars are sometimes rolled in open pass rolls and many times are rolled in tongue and groove rolls.

Sheets—The practice covering the rolling of sheet and strip is given on page 818.

Fig. 2—Passes and reductions of a 4x4 in. billet to a $\frac{3}{4}$ in. round bar.

Fig. 3—Shapes rolled from ingots.

Shape Rolling—Steel is rolled into many varying shapes and special passes are made in rolls, depending upon the shape of the finished product. In the majority of cases, these shapes are rolled from a square or rectangular bloom or billet, all the shaping being done in the intermediate passes of the mill. In some cases, however, the shape of the finished product controls the preceding operations as far back as the ingot (Fig. 3).

Forging—Forging is used as a general term to describe the method of hot mechanical working of steel by the use of hammers, presses, and forging machines. A distinguishing point in the working of steel by forging is that the working for reduction or shaping takes the form of a locally applied force which displaces the metal under compression, after which

it is relieved and a new portion subjected to the working force. In rolling steel, the force is exerted by passing the material between constantly rotating rolls, and hence is continuously progressive in nature. A simple conception of the two processes is that forging exerts more of a kneading or hammering action, while rolling is more of the nature of a drawing operation (Figs. 1 and 4). For specific forging practices, see articles in this Handbook on forging.

Hammering—All steam hammers made today, except drop hammers, are double acting; that is, the falling weight or die is driven down onto the work by

steam. This increases the velocity of the head and increases the power of the blow.

The steam hammer consists primarily of a rigid frame supporting at the top a vertical steam cylinder. The piston is on the upper end of a rod which has the hammer head, termed "ram," and upper die at the lower end. The valve controlling the admission and exhaust of the steam is controlled by a lever usually attached to the lower part of the frame. The lower die and anvil is on a separate foundation from the remainder of the hammer in order to take the shock.

Various other types of power hammers find special uses today. Some are actuated by compressed air, others by motors.

Action of Hammering—The action of the hammer on the mass of hot metal is different from that of either the rolling mill or the press, because it strikes a more

or less sudden blow. The pressure is applied to the metal for a moment only, and before the metal has fully yielded, it is relieved. The metal, being elastic, recovers somewhat. For this reason, penetration of the effect of hammering tends to be limited. The surface of the metal is worked perfectly, whereas the center, if the piece is large, may hardly be affected.

Pressing—As the need for larger forgings grew, correspondingly larger ingots were cast. It was found that larger ingots had looser textures at the centers, and that it was difficult to thoroughly work these central portions under the hammer.

Fig. 4—Action of forging.

Forging presses consist essentially of a cylinder into which water at high pressure is admitted. The cylinder is located at the top of the press. The admission of water into the cylinder pushes down a ram to which is attached the cross head, on the lower side of which the upper die is fastened. The cylinder is held by vertical columns, which usually act as guides for the cross head. The lower die is supported on a base plate held by these columns at the lower ends. Thus the whole unit is self contained. Auxiliary lifting

cylinders, supplied with either steam or water are usually attached to the main cylinder or its entablature.

Tools for Hammers and Presses—Tools similar to those used by the blacksmith are applied to the steam hammer, such as tongs of different sizes with jaws of shapes suitable to handle the work. Swages are a form of semicircular die for finishing round bars. Heading tools and bolster blocks are used to forge upset ends on shafts. Forgings too heavy to be held on the dies by man power are carried by large tongs supported by a chain. Larger forgings are fastened onto a porter bar by means of a chuck on the end of the latter.

Rectangular sectioned blocks, held under the hammer on long rods, are called "pegs," and are used as gages or spacing blocks in bringing forgings down to size. Slicing bars are used to cut off and turn forgings.

Working under the press is simplified by the absence of shock in the process. Forgings can be held on the dies by direct suspension from cranes. Chain slings are used for the largest types, and the chain runs over a power sprocket on the upper end so that the forging may be turned; in some instances turning is done by ratchet levers. Many varying types of manipulators are used, suspended from overhead cranes, or running on tracks on the floor, which are designed to hold one end of the forging in a grip and move or turn it to any desired position.

Fig. 5—Simple forms of forging dies.

Hammer Dies—The sizes and shapes of dies used under the steam hammer are many and varied and depend on the tools, the forgings to be made, and the forging practice followed. For the manufacture of bars or forgings similar to shafts, flat dies are usually used with the hammer, and the reduction from the ingot generally takes the bar to the form of a hexagon or octagon. It can subsequently be rounded up by knocking off the

corners of the polygonal section, or better, it can be finished with a top plain die and a bottom V. For the smoothest finish the bar may be trued up between swage dies each of which is practically semicircular. If this type of die is used, not much further reduction is often needed. Many round shafts are finished between flat dies on the hammer, ending up with a series of very light or "saddening" blows. Swage dies are generally used for tool steel bars. Simple forms of forging dies are shown in Fig. 5.

Press Dies—The dies used on a press are similar to those used on the hammer except that V-shaped bottom die is more general. The greater the power that can be exerted by the press, the larger the die surface that can be used, and therefore the more effective the press can be in working the central portions of the mass to be forged. It is also possible on the press to use a very narrow top die for expanding or drawing out the metal in any one direction.

Hammer and Press Operations—Except as covered in the next section, the principal forging operations performed either by the hammer or press are as follows:

1. Rounding up, cogging, or roughing. These first operations on the ingot aim to refine and rearrange the surface crystals and to consolidate the central portion of the ingot.

2. **Cutting or slicing.** This operation cuts blocks, billets, or forgings to length.

3. **Forging down or drawing.** This operation increases the length and decreases the diameter of the billet.

4. **Upsetting the forging** in a direction perpendicular to the longitudinal or major axis.

5. **Setting down.** This reduces the cross-sectional area of a portion of the forging, as the journals of a shaft are forged down. Large "set-downs" are accomplished under the press, using a V-tool to start the reduction. Large fillets should always be allowed.

Hollow Forgings and Piercing—Many machine parts require forged cylinders or similar sections. Large rings, cylinders, or hollow shafts can be advantageously worked in this way. For this purpose the ingot or block is pierced, punched, trephined or bored. As the name implies, piercing consists of boring into the mass with a pointed punch. The punch has to be of a material hard enough to penetrate, resist abrasion, and not be too severely affected by the temperature. Cylinders with one solid end may be pierced while held in a cylindrical die. In cases of this sort, the pointed punch would be followed by successively larger, slightly tapered, and blunt nose punches to increase the bore and forge out the walls of the cylinder against the die.

Punched Forgings—Blocks intended for ring or similar forgings are often punched under the hammer or press. The punch may be in the form of a tapered cylinder with a slightly rounded flat nose. It is usually pushed part way through on one side, the forging turned over, and the hole punched through from the other side with a slightly larger punch.

Forged Expanded Rings—Rings may be expanded under the hammer, using a horn attached to the bottom die. Large rings are expanded under the press on a mandrel, supported on standards close to the ends of the forging. Large cylinders are drawn out on mandrels under the press, the mandrel being supported for expanding, and unsupported for forming to shape, using a top plain die and a bottom V die.

Hot Die Forging (Drop Forging)

By R. W. Thompson*

Die forging conducted under a hammer is most commonly referred to as "drop forging." It is the operation of forming a metallic shape by repeated blows on a bar or billet between a pair of dies which have the desired impression of the finished forging shape.

The drop forging hammer contains a ram which carries a die operating in a vertical plane and an anvil block in which is keyed a stationary die. The two dies are matched together so that the impressions in each are in perfect alignment permitting the impact to cause the metal to fill the cavities for the production of the prescribed forging design. The means by which the ram is lifted determines the name by which the hammer is known.

Steam Drop Hammers—The ram and movable die are actuated by a steam valve which regulates the height of drop and force of the blow through the action of a piston rod operating in a steam cylinder. These hammers are known as double acting hammers, because the steam is utilized for lifting the die upward, as well as for forcing it downward. Steam hammers range in capacity from 500-50,000 lb. and are so rated on the basis of the combined falling weight of the ram and piston rod. Because of their great force of impact and rapid operation, steam hammers are generally used for drop forging the heavier forging parts and also those designs which require numerous hammer blows to complete the various die operations in their manufacture.

Air Drop Hammers—Hammer construction is the same as for steam drop hammers with the exception of the valve mechanism. Power is derived from compressed air instead of steam and with operation equally satisfactory. The selection of air for power is a matter to be judged by the economical advantages offered in the particular plant or location.

Board Drop Hammers—In a board drop hammer the ram is lifted by means of one or more boards keyed to the ram which pass between two rollers at the top of the hammer. The boards are rolled upward and then mechanically released, permitting the ram to drop when the desired height is reached. The power for this operation is either by direct motor drive or by line shaft and pulleys.

In the board drop hammer the force of the impact is dependent upon the gravity attraction of the ram and for this reason it is sometimes known as a gravity hammer. These hammers built to standard specifications have a falling weight or capacity of 400-10,000 lb., and naturally are used in the production of the smaller and lighter forging parts.

Helve Hammers—Some die forging is conducted with hammers in which the force is not dependent upon the vertical fall of the ram. This type of die forging work is not ordinarily considered as drop forging. These hammers operate by an oscillating wooden beam pivoted at one end and carrying at the free end the ram head and movable die. The beam is lifted by a rotating shaft carrying a series of cams which raise the hammer and allow it to drop suddenly in a succession of blows with lightning-like rapidity.

Forging hammers of this type do not deliver a very forceful blow and therefore depend upon their fast and continuous operation for forging production. Only small forging designs are made with these hammers, being used more often as an auxiliary unit in conjunction with a drop hammer wherein they serve to draw or reduce certain sections of a forging part.

Dies and Tools—A blueprint or sketch of the forging showing the necessary draft angles, radii, fillets, and amount of finish required, is submitted to the die shop for their guidance in making the dies for the forging. It is the purpose of the forging dies to produce as many forgings as possible, each to the tolerances prescribed and commercially duplicates of each other.

Forging dies are designed so as to give the required mechanical working to a bar or billet in order to produce the finished forging shape with a minimum of

* Sales Engineer, Transue & Williams Steel Forging Corp., Alliance, Ohio. Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steever, chairman, J. H. Friedman, R. W. Thompson, F. B. Foley, W. W. Criley, H. M. Spears, W. E. Jominy, and O. W. Ellis.

internal stress. Their construction is also designed so as to maintain the grain fibers inherent in the rolled bar in a continuous and unbroken manner in the forging and whenever possible at right angles to the direction of stress or shock in service.

Forging dies for small forgings are oftentimes designed with multiple impressions, producing several pieces in one flashing. The use of a larger hammer in producing the forgings in multiples is generally thought more economical, providing sufficient quantities are to be made to justify the extra die expense.

Die blocks in most general use are made of alloy steel and are heat treated to a hardness which is governed by the size of the block and the design of the forging for which they are to be used. It is common practice to use dies hardened before sinking when the hardness required is less than 60 scleroscope. For dies requiring a hardness of 60 scleroscope or over, the hardening of the blocks is conducted after the die sinking is completed.

The necessary impressions in a die for a certain forging may be described as fuller or swager, edger or roller, blocker, finisher, and cutoff. The fuller reduces the side of the section of the material. The edger conforms the material to the area of the respective sections of the piece to be forged. The blocker gives the forging its general shape, and the finisher completes the forging design. The cutoff is used to cut the forging from the bar so the operations may be repeated.

In addition to the impressions which are used for the various operations of drop forging production, the dies are also provided with a gutter, which is the portion of the die around the impression that has been relieved to provide space for the excess stock.

Standard draft angles in the dies of 7° are in general use, although quite often in cases where forgings are designed with deep holes it is desirable to use 10° draft for better forging results. The draft or taper on the side walls of the die impressions are necessary for the removal of the forging from the die, and should be taken into consideration at the time the forging is designed.

After a set of dies has been completed, the two halves are matched together and molten lead and antimony are poured into the finishing impression, producing a model of the forging which is known as a lead cast. The lead cast is used for checking purposes and is measured with a shrink rule which compensates for the shrinking of the material. The amount of shrinkage varies a little with the type of material and shape of the forging, but may be generally considered as $\frac{1}{8}$ in. to the foot.

The flash or excess metal forced out between the dies in filling the impression to its complete contour is trimmed from the forging in a mechanical press. Trimming dies are furnished for either hot or cold trimming, depending upon the method desired. Hot trimming is done on large forgings and certain alloy steels which would fracture if cold trimmed, and usually is conducted in a press adjacent to the hammer at the time of the forging operation. Small forgings are usually trimmed cold. They are likewise trimmed in a press and most generally in a separate department.

Trimming dies are made of tool steel and are shaped to fit the outline of the forging at the parting line of the dies. The trimming punch, also of tool steel, is shaped to the contour of the top of the forging to be trimmed. The trimming tools for cold trimming are always quenched and tempered to a hardness that will produce the best wearing and cutting edges for the particular forging design. Hot trimming tools, except trimming dies, are usually quenched and tempered, but are sometimes used in either the annealed or normalized condition. Trimming dies are either quenched and tempered or surfaced with a hard facing alloy.

General—Drop forging operations are conducted by working from the bar end, cut slug, and individual billet. In working from the bar, one or more forgings are made before the end of the bar is reheated. The number of forgings cut off at each heating is dependent upon the size and design of the forging.

Cut slugs of a weight necessary for the forging of one piece are forged by the hammer upset method. The slug is placed on end on the die and upset or pancaked to form the forging. This method has a particular advantage in the control of grain fibers and is used generally in the production of gear blanks, hubs, and flange forgings.

Forgings of medium and larger sizes are made from billets sheared or sawed to the individual length required for the production of one piece. Large and massive forgings oftentimes require two or more hammers to effect their com-

pletion; each hammer providing progressive steps by aid of proper dies and tooling for the necessary operations.

In forging the bar or billet into a completed drop forging design, the metal is further refined into a dense tough fiber structure throughout the entire cross section. This refinement of the forging bar improves the physical properties, increasing the impact, tensile, torsional and compressional strength.

For information on heating, see the article in this Handbook on "Heating Steel Bars for Forging."

Inspection—Forgings are checked periodically during hammer operations for mismatch, dimensions, and tolerances, as well as for detection of laps, cold shuts and seams.

After trimming, the scale or surface oxide is removed by any one of a number of methods. The principal ones are pickling, sand or shot blasting, and tumbling.

The final inspection, in addition to a recheck of conditions examined for during hot inspection, may be further classified as to mistrimmed, scale pits, not filled, underweight, overweight, and any physical or microscopic tests prescribed in the specifications.

Hot Upset Machine Forging

By W. W. Criley*

Definition—Hot heading, upset forging, or more broadly machine forging are terms applied to the hot deformation or plastic flow of steel in an upsetting forging machine commonly in use. It primarily consists of holding a bar of uniform cross section, usually round, between grooved dies and applying pressure with a heading tool on the end in the direction of the axis of the bar so as to upset or enlarge the end.

Description of Forging Machine—Present day forging machines, some of which weigh in excess of 200 tons, and are capable of 2000 tons pressure, are an outgrowth

Fig. 1—A plan view of a forging machine showing arrangement of working parts.

of earlier small machines built mainly for hot heading bolts and for producing nuts by an added punching operation. Such machines were rated on the basis of the maximum size bolt they were capable of heading, and this method of rating has, after a fashion, been adhered to and extended to include even the largest machines, while the same fundamental forging processes are employed to produce a great variety of upset and pierced forgings, weighing from a few ounces up to several

hundred pounds. Any of the malleable materials can be forged by this method of compression deformation including wrought iron, alloy steel, copper, bronze, aluminum and others.

A plan view of a forging machine is given in Fig. 1. The machines in general use are mechanically operated from a main shaft which drives a main or header slide horizontally by means of an eccentric and pitman, and also drives a die slide or grip slide with horizontal movement at right angles to the header slide, usually through a toggle mechanism. Power is supplied to the machine flywheel by electric motor or line shaft, and, excepting on small continuous motion machines used for forging and shearing off bolts and rivets from long bars, a clutch provides for "stop motion" operation, placing the movement of the slide under the control of the operator.

The die elements in which forging takes place consist of two "dies" or "gripper dies," one stationary and one moved by the die slide, which have matching faces with horizontal grooves to grip and hold by friction the forging stock, and "headers" or "heading tools," carried by the header slide in the plane of the die work faces, and matching the die impressions. The travel of the moving die is designated as the "die opening" and its timed relation to the movement of the header slide is such that the dies close during the early part of the header slide stroke. That part of the forward header slide stroke which takes place after the dies are closed is termed the "stock gather" and the amount of header slide return travel before the moving die starts opening is called the "hold on" or simply "hold."

For forging, the operator places a bar of forging stock heated on the end in the first groove in the stationary die against a movable stock gage to secure the correct volume of stock in the forging impression. When he trips the clutch, the moving die closes, grips the stock and holds it while the heading tool advances and

*General Manager, The Ajax Manufacturing Co., Cleveland.

Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steever, chairman; R. W. Thompson, F. B. Foley, O. W. Ellis, H. M. Spears, W. E. Jominy, W. W. Criley, and J. H. Friedman.

upsets the end of the bar which projects beyond the gripping grooves and is termed "working stock." The operator then transfers the bar to other die grooves, striking it generally but once in each groove, the number of grooves depending upon the steps required to complete the forging.

Forging is not limited to simple gripping and heading operations, as the transverse action of the moving die and the longitudinal action of the heading tool is available for forging in both directions, either separately or simultaneously. The die motion, in addition to gripping, can be used for swaging, bending, shearing, slitting, punching and trimming; and the heading tools, in addition to upsetting, are used for punching, internal displacement, extrusion, slotting, trimming, bending and other operations.

As the cavities formed by the two dies and the heading tools open in two planes at right angles, and as the working stock can frequently be totally confined in these cavities during forging, and subjected to a hydrostatic-like pressure causing it to completely fill the impressions, a great variety of shapes can be forged and removed from the dies without difficulty as shown in Fig. 2.

Forging Machine Requirements—In order to produce forgings to the close Standard Tolerances drafted by the Drop Forging Association, February 11, 1937, accurately filled out and free from defects, the modern forging machine must have (1) a rigid frame with minimum transverse and longitudinal distortion under forging pressures; (2) a powerful die grip to hold the stock securely and prevent the dies from spreading open with resultant formation of flash; (3) accurate die slide and header slide alignment to prevent mismatch of the impressions of the two dies and heading tools, and to produce deep concentric holes; (4) ample heading power to forge to accurate thickness and drive the stock into remote parts of the die impressions to properly fill them; (5) a fast starting clutch and operating convenience so that the multiple operations required to produce difficult forgings can be performed before the working stock loses its forging temperature.

"Die opening" is the factor which determines the maximum diameter upsets which can be formed on a given machine, transferred between the dies, and withdrawn through the throat without pushing forward of the dies and lifting out over the top. The "stock gather" determines, not so much the amount of stock that can be upset, as the diameter of stock itself, but has important bearing on the depth to which internal displacement can be carried in a single operation. The die height determines the number of progressive operations which can be accommodated in one set of dies.

Die Construction and Design—Proper dies are also essential to the production of sound forgings. So that impressions will retain their correct shapes, particularly at the part line, the dies must be constructed of suitable grades of die steel for hot work with resistance to heat, pressure, and abrasion, and selected with reference to the specific properties required, the speed of forging, and the quantity of forgings to be produced. See *Steels for Forging Dies*, page 1018. The absence of impact in this method of forging makes it possible to build up dies with inserts, thereby, without prohibitive cost, utilizing a variety of high grade steels to exactly meet the needs at different locations in the impressions. This gives increased durability and makes the more vulnerable points inexpensively renewable. Fig. 3 illustrates inserted dies and tools for upsetting gear blanks.

Factors Governing Upsetting—The number of operations employed to produce a forging are determined by the length and diameter of working stock, the shape

Fig. 2—A group of upset forgings, some of which show the successive forging operations.

of the forging itself, and any special internal fiber arrangement necessary to produce the desired physical properties in the finished forging. Successive upsetting operations should each fill the die cavity completely, consequently be of the same volume and sound, as subsequent operations rather than ironing out defects, tend to imbed them. The most common defects to be avoided are cold shuts, that is, closed folds in the surface metal, re-entering fiber or internal folds, and included flash.

The generally recognized rules governing the upsetting or gathering of stock without injurious bending and resulting cold shuts are:

Fig. 3—Inserted dies and tools for upsetting gear blank with a final combined shearing and punching operation with progressive forging steps and section showing looping fiber arrangement of completed forging.

I. Working stock up to a maximum length of three diameters can be upset without support to prevent bending. Working recommendation $L = 2\frac{1}{2}d$.

II. Working stock longer than three diameters, in order to prevent injurious bending, must be supported by either die or heading tool impressions of a maximum diameter of one and a half times the diameter of the working stock. Working recommendation $D = 1\frac{1}{2}d$.

Die Impressions should be as nearly the full length of the working stock as will permit gaging, and the recess in heading tool should be at least two-thirds the length of the working stock and belled at the opening to prevent a sharp shoulder. Supporting impression should not be partly in the die and partly in the tool.

Repeated applications of the second rule make possible the upsetting of great lengths of original bar stock, and with the progressive increase in the diameter of the "working stock," the amount of "stock gather" can be increased on succeeding operations. Preference is given to recessed heading tools for stock gathering, owing to their greater durability and freedom from the flash, which tends to form at the die part-line when upsetting in grooves in the die and around the periphery of the plunger-like heading tool.

Square stock is governed by the same rules as round, using "d" as the mean of the flat and diagonal dimensions, but rectangular stock bends so easily flatwise that the short rectangular dimension is the one that must be used in the above formulae.

Fiber Arrangement—In gear forgings particularly, and other highly stressed parts, effort is made to secure maximum strength through advantageous internal fiber arrangement, as illustrated in Fig. 3. This can be controlled by the shape of the preliminary upsets, and re-entering or sharply folded fiber can be avoided. Progressive operations should be shaped so as to be easily filled by hydrostatic pressure within the hot metal.

Flash—Flash can be avoided best by locating the part line between the heading tool and the die at the point of the impression which fills last, and, if flash is unavoidable, it should be located where it can be easily removed by trimming, chipping or grinding.

Pierced Forgings—Internal-recessed, or deep-pierced forgings are produced most easily by the progressive piercing method as contrasted with extrusion. In this method, as illustrated in Fig. 4, the metal from the interior of the full length blank

Fig. 4—Progressive steps in deep piercing a shell by internal displacement method, showing cross section of progressive operations in die impressions prior to being acted upon by piercer.

is progressively displaced to the outside of the die cavity without excessive pressures or abrasive flow to cause rapid deterioration of the die elements.

Tubular Upset—With the extensive use in the oil industry of seamless steel tubing with threaded joints of full body strength, and the use of both seamless and welded tubular structural members, where minimum dead weight and maximum strength are required, the upsetting of tubing has assumed importance. Light wall thickness being easily collapsible, offers difficulty in gripping between the dies to prevent slippage, frequently necessitating the use of a backstop; rapid cooling makes reheats necessary; and the wall thickness limits the extent to which upsetting can be carried in a single operation without injurious folds. Since buckling occurs to the outside, an increase in wall thickness of only about forty per cent can be accomplished by a single outside upset; whereas, with the outside closely supported by the dies, the wall thickness can be practically doubled by a single inside upset. This makes it advantageous, where permissible, to gather the stock with internal upsets, then force this stock into an external impression by means of a tapered nose on the heading tool.

Since each upset forging offers its own particular problem, each must be handled on an individual basis in a manner adhering to the broad fundamentals of sound upset forging practice.

The Piercing of Steel

By Stevenson Findlater*

The forging operation in the production of seamless steel tubes is classified under four general headings: rotary piercing, hydraulic piercing, cupping, and extrusion. Of these four methods, rotary piercing is employed almost universally for quantity production.

Rotary Piercing—In the rotary piercing of steel (Fig. 1), the principle of helical rolling is employed. The two steel rolls which bring into play the forces used to produce the cavity in the work piece are positioned side by side and have their axes inclined at opposite angles (6-12°) with the horizontal centerline of the mill. The shafts of these rolls are mounted in bearings, which can be adjusted laterally in

Fig. 1—Mannesmann pierces, piercing solid billet.

Fig. 3—Cupping operation, plate.

Fig. 4—Extruding solid billet.

the housing to permit the space between the rolls to be properly set for the size of work piece being rolled. The roll surfaces are contoured so that in a horizontal plane through the centerline of the pass, the space between the rolls converges toward the delivery side for a length of about ten in. to a minimum, called the "gorge," and then diverges for approximately twelve in. to form the pass outlet. The elevation of the centerline of the pass is determined by two guides, one of which is mounted above and the other below the center of the mill.

Between these guides in the pass outlet a tapered piercing mandrel is held in position on the end of a water cooled mandrel support bar located on the delivery side of the mill. The opposite end of this bar is mounted in a thrust bearing which is carried in a reciprocating carriage that is latched stationary during the piercing

*National Tube Co., Pittsburgh.

operation. The pointed end of the piercing mandrel extends just beyond the gorge toward the entering side of the rolls.

A solid round bar or billet of the proper length and diameter (2-14 in. dia. by various lengths to 18 ft.) to make the size and weight of tube desired, is heated uniformly to the usual temperature for rolling light sections. With the rolls revolving at a constant speed (800-1000 surface ft. per min.) the heated billet is transferred to a horizontal trough which positions the axis of the billet coincident with the centerline of the pass.

The heated billet is pushed forward into the space between the rolls, which has been adjusted so that the gorge is approximately $\frac{1}{4}$ in. less than the dia. of the billet. As soon as the billet has contacted the rolls, the force of the pusher is removed. Owing to the obliquity of the roll axes, the motion imparted to the billet by the rolls is one of rotation and axial advance. When the leading end of the billet has advanced to the gorge, it encounters the nose of the piercing mandrel. The grip of the rolls is sufficient to continue the advance of the work piece against the retarding effect imposed by the piercing mandrel. Once the end of the piercing mandrel has penetrated the axial center of the billet, the mandrel serves as a third roll so that, with a properly designed pass, the metal of the work piece is helically rolled over the piercing mandrel (rather than extruded) to produce the hollow shell. These shells are produced in lengths up to 40 ft., in from 10-30 sec. It is to be especially noted that the amount of metal displaced increases considerably as the size is increased. Difficulty with this condition has been overcome by further reducing the wall thickness of the hollow shell through additional rolling in a second piercing mill. This practice has permitted the total displacement to be divided between two operations when large tubes are made. Additional rolling operations are performed on the pierced shells to produce finished tubes.

Hydraulic Piercing—In hydraulic piercing, a heated solid blank, usually of square section, is dropped into a cylindrical container located directly in line with the plunger of a hydraulic ram. The descending plunger causes the piece to assume the shape of the cylindrical container as it is displaced up and around in the space between the plunger and container. When the down stroke has been completed, the plunger is withdrawn by reversing the direction of the ram, after which the pierced blank or cup is ejected by a kicker pin. When this process is augmented by hot drawing, whereby a powerful plunger forces the cup through a push bench in which a series of annular dies or grooved rolls are installed, the length of the piece may thereby be extended to form a tube.

Hydraulic Piercing (Fig. 2) is used in the production of large and small cylinders, such as water bottles, gas, and air bottles, and as the primary operation in manufacturing tubes by the "push bench" method.

Cupping—In the cupping process (Fig. 3), steel plate of required thickness is sheared, machined or gas cut to circular shape. The heated plate is accurately positioned over a die which is centrally located beneath the plunger of a hydraulic ram. The descending plunger forces the plate through the die to form a cup which is removed when the plunger has been withdrawn. To avoid buckling when cupping, the annular opening between the plunger and the die is proportioned to exceed the initial thickness of the plate. Requisite alterations in the length, wall thickness, and diameter of the heated cup are subsequently made in a push bench. This process is in common usage in manufacturing containers for oxygen and acetylene and for other cylinders which require a closed end.

Extrusion—The extrusion process (Fig. 4) has not been used for the production of steel tubes in the United States, although several European plants employ it. The elevated temperatures essential to effect the necessary plasticity of a steel work piece requires that the operation be rapid to avoid temperature drop and severe tool wear during the working stroke of the press. This requisite has resulted in the development of the practice known as "impact extrusion" in which the work stroke in extruding tubes 30 ft. long is completed in less than three seconds. In this process, either bored or solid rounds are heated and dropped into a cylindrical container, in the bottom of which a die is mounted directly below a crank or hydraulically operated plunger. When solid rounds are used, a differentially actuated piercing punch is enclosed within the extrusion plunger. In operation, the weight of the extrusion plunger is allowed to rest on the upper surface of the work piece, while the piercing punch is forced through the work piece and die. When the end of the piercing punch has passed through the die, the piercing and extrusion plungers are locked together, permitting the piercing punch to act

as a moving mandrel, while the rapidly descending extrusion plunger forces the work metal through the annular opening between the die and piercing punch. Pressures in excess of 90,000 psi. are produced within the container in producing the 20:1 section reduction usually employed. When the plungers have been withdrawn, a flash which remains in the bottom of the container is sheared off, thereby releasing the extruded tube from the die.

When bored rounds are used, the piercing punch is usually attached directly to the lower end of the extrusion plunger. The operation is the same as when solid rounds are used, except that piercing is omitted.

Because of the terrific pressure required, the application of the extrusion process to the manufacture of steel tubes has been limited to tubes less than 5 in. in dia.

Steels for Piercing—The piercing processes described above have enabled seamless tubes to be made from most types of steels and many nonferrous alloys. Usually, killed open hearth and electric furnace steels are preferred, but satisfactory seamless tubes have been made from capped open hearth steels when melted under certain prescribed conditions.

Most commercial steels are available as seamless tubes. The S.A.E. steels, high sulphur free machining steels, ball and roller bearing race steels, and many stainless and heat resistant alloys are now satisfactorily pierced. In general, steel alloys which are two phase, austenitic and ferritic, at forging temperatures (2000-2300°F.) are difficult to pierce by the rotary process but can be formed in the cupping or extrusion processes. Nonferrous alloys which contain more than one phase are also more readily pierced by extrusion methods. Extrusion is little used on steel because the high forging temperatures and high pressures are severe on extrusion tools, but the process has been highly successful on nonferrous alloys.

The steels used for seamless tubes must have good characteristics, both with respect to surface and internal soundness, on account of the severe forging operations involved in piercing. Sound dense steel, as shown by deep etching tests on cross sections, free from porosity and ingot pattern, is most satisfactory for seamless tubes. Tube steels must also be free from surface defects, so it is common practice before piercing to peel rounds or plane square sections in addition to treating them by conventional chipping methods.

Extrusion of Metals

By D. K. Crampton*

Introduction—The term "extrusion" as applied to metals comprises essentially the application to a relatively massive billet or blank sufficient pressure to cause the metal to flow through a restricted orifice, thereby forming a greatly elongated section of uniform but relatively less massive volume. The extrusion may be either hot or cold. As the terms indicate, hot extrusion is above the recrystallization point of the metal which continuously recrystallizes and is not work hardened during the process. In cold extrusion the metal never reaches the temperature of incipient recrystallization. It may, therefore, be considerably work hardened by the process.

Both mechanical and hydraulic extrusion presses are used but the tendency today is almost exclusively toward the hydraulic type. These are more flexible, compact, easier to control, and less subject to damage from improper operation. The presses most used at present vary in capacity from 200-4000 tons.

Hot Extrusion of Lead and Lead-Base Alloys—The ordinary extrusion of low melting point metals such as lead, tin, zinc, lead-tin alloys, pewter or britannia metal is usually carried out either at room temperature or at least fairly low temperatures.

Fig. 1—Section through die block assembly used in making lead cable.

The pressures required to extrude will vary considerably with the alloy as well as with the temperature, size of section, and number of sections per die. Soft lead usually will require unit pressures from about 40,000 to about 60,000 psi. For any given section the copper-bearing leads will require roughly 10-20% more pressure, and the antimonial and tin-bearing alloys possibly 50% more.

The speeds permissible also vary greatly. With soft and copper-bearing leads and large sections, this is limited only by the capacity of the pumps. In small sections it may in some instances run as high as 200 ft. per min. However, with the other alloys mentioned, speeds of from 20 to not over 80 ft. per min. are necessary to prevent checking. The physical properties vary somewhat with the speed, better values resulting from the lower speeds.

Cable Sheath—The equipment for extruding cable sheath includes a melting kettle with connection to the extrusion press. The usual press is hydraulic and so arranged as to take intermittent charges of molten lead from the kettle. This press is vertical, and the cylinder in a commercial machine might hold approximately 1800 lb. of lead. At the lower end of the cylinder, there is a die block forming an annular path for the flow of lead around a core through which is fed the cable to be sheathed. A section through a die block assembly is shown in Fig. 1. The molten lead is charged into the press at about 750°F. and it normally requires approximately 7-8 min. for solidification and reduction to a suitable temperature for extrusion (about 425°F.) at which time the pressure is applied. The now solid lead is forced through an annular orifice between the core block and the die and

*Director of Research, Chase Brass and Copper Co., Waterbury, Conn.

on to the cable, the product normally being coiled on a large drum as it comes from the press. The presses commonly used for this work have a capacity of from about 600-2500 tons and can produce up to 5500 lb. per hr. or slightly better.

One of the difficulties encountered in the finished cable sheathing is a seam due to entrapping oxides or other foreign materials between successive charges of lead. There is, of course, at all times a layer of dross on the surface of the molten lead and even with the utmost care, some of this may be entrained, tending to prevent perfect coalescence of the divided lead stream as it flows around the core block or at the interface between two successive charges of lead fed into the cylinder. When an appreciable quantity of such dross is occluded a seam or a weak spot results, which is likely to fail in service.

Hose Encasing—In the manufacture of rubber garden hose and of rubber covered wire it is common practice to vulcanize the rubber while it is encased in a sheath or mold of lead. This lead mold is extruded over the hose in quite similar manner to that used in the production of cable sheath. In the present instance, precast lead billets are fed into the press instead of molten lead. This is possible because no particular precaution against forming of seams or the inclusion of dross need be taken. By eliminating the necessity of waiting for the molten metal to freeze, approximately double the production is obtained.

While cold billets may be fed, they are preferably heated to about 260°F. The container itself ordinarily is heated to a temperature of approximately 350°F., and the actual temperature of the lead, as extruded, approximates the latter figure. Pure soft lead is ordinarily used, and this is extruded as fast as the equipment permits, speeds up to 100 ft. per min. being attained. After the lead encased hose is taken from the press, it is vulcanized by hot water under pressure which varies from 150-250 lb. pressure. The lead is subsequently stripped from the hose and is remelted for further use in the same operation. Under ordinary conditions billets weighing approximately eleven to twelve hundred lb. are used, and the lengths obtained depend upon the size of the hose encased. The lengths run from 250-1000 ft. in normal production.

Lead Pipe—Vertical presses are used for extrusion of lead pipe. Usually, but not always, the lead is poured in and solidified before extrusion. The die is held in the hollow ram and the extruded pipe comes out at the top of the press and is coiled as produced. The presses commercially used normally run from about 400-1000 tons capacity and the individual charges vary from 200-500 lb. depending upon the size of the pipe made. Soft lead can be extruded quite fast, the speed being determined largely by the capacity of the pumps. Speeds of 50-60 ft. per min. are not uncommon in practice.

Hot Extrusion of Tin-Base Alloys—Various solder alloys are extruded in the form of wire. These are mostly tin-lead alloys containing from about 40-80% tin. Many other tin-base alloys are produced in lesser amounts. A large part of this production is in the form of solid wire, but a considerable amount also is resin or other flux-cored solder. In the case of the solid wire, solid billets are extruded in an ordinary rod extrusion press, but in the case of flux-cored solders, resort is made to a procedure roughly similar to that employed for hose encasing or cable sheathing. The presses used for solders may be either vertical or horizontal but are small, ranging from about 200-500 tons and using billets about 2½-4 in. in dia. and 8-16 in. long. Resin core solders are extruded in a single strand, but solid wires in multiple strands, sometimes as many as 12 per die.

Most solder alloys must be extruded at fairly low speeds to prevent checking of the surface, about 30 ft. per min. being usual. The pressures and temperatures run about the same as in the cable sheath extrusion.

A considerable quantity of various ornamental shapes are extruded from pewter, or as it is sometimes called, britannia or white metal. The alloy is of variable composition, of tin-base, and normally contains anywhere from 5-15% antimony, from 0-3% copper and 0-15% lead. These extruded shapes are used for moldings on various pewter pieces such as vases and pitchers. They are attached to the plates by the use of low melting point solders.

An ordinary horizontal rod press of about 250 tons capacity is used, the billets being about 2½ in. in dia. by 8 in. long. The alloy is extruded at a temperature of 140-150°F., but very low speed must be used to prevent checking of the edges. In some cases this might be as low as 10-20 ft. per min. The pressures used will vary from 40,000-100,000 psi.

Hot Extrusion of Copper and Copper Alloys—The equipment used for extruding copper-base alloys is different in many respects from that employed for the low melting point alloys although the principles involved are much the same. Both mechanical and hydraulic presses have been used but the mechanical ones are much in the minority and the present tendency is entirely toward the hydraulic.

Rods are always extruded from horizontal hydraulic presses, but for tubes both horizontal and vertical ones are used. For tube extrusion the smaller presses of capacities up to perhaps 1100 tons are prevaillingly vertical and the larger ones invariably horizontal. Tube presses up to 4500 tons are in use and rod presses up to about 3500 tons.

The extruded nickel silvers are used mainly for their white color, high strength and fair machinability. While they can be extruded quite readily, the permissible temperature range is narrow compared to the other extruded alloys and it is relatively difficult to extrude them in small sizes or very complicated sections.

The linear speed of extrusion in rod presses varies enormously with the composition of the alloys, the size and shape of the section, the temperature and the presence or absence of an accumulator. In rod presses, speeds from approximately 20 to well over 500 ft. per min. are commercial. In tube extrusion presses using an accumulator, the linear speed is in some instances as high as approximately 1000 ft. per min.

The pressure required to extrude also varies quite widely depending on much the same factors as those which control speed. With the softer alloys, larger sizes, and simpler shapes, pressures as low as approximately 30,000 psi. are used. With harder alloys, more complex shapes and relatively smaller sections, pressures up to 120,000 psi. are found necessary. In general, when the press is operated direct from the pumps, the pressure required to start flow through the die is fairly high. Immediately after starting, the pressure falls to a fairly low figure which holds relatively constant until near the end of the extrusion when the pressure may rise to at least double that required for starting. This effect, as well as the marked effect of temperature, are both shown in Fig. 2.

Rods are usually extruded straight, on to either a stationary or traveling cooling bed, and are subsequently drawn to finish. Any material which is ultimately to be drawn into rather small diameter rods or wire is normally extruded in sizes from about $\frac{3}{8}$ - $\frac{1}{2}$ in., depending on the alloy, and coiled hot as it comes from the die. In these smaller sizes, several rods may be extruded from a die, sometimes as many as four. Two-hole dies are commonly used up to about 1 in. but larger rods are invariably extruded through a single hole die. "Pipe" is a defect more or less inherent in the extrusion of brass rods and is caused primarily by the flow of the oxidized surface of the billet to the center during the extrusion process. In the higher copper content alloys having a single alpha solid solution structure little or no central pipe is incurred, because the oxidized material comes to the surface of the extruded rod, frequently giving the appearance of a shag bark hickory tree. In such instances the defective surface has to be removed by scalping before the rods can be drawn to final size. In Table I and II are given the copper-base extruding alloys and their physical characteristics.

Hot Extrusion of Aluminum-Base Alloys—The equipment used for extruding aluminum alloys is similar to that employed for the copper alloys. The presses are usually horizontal ones with capacities ranging from about 500-4,000 tons.

Although practically all aluminum alloys can be extruded if necessary, only a

Fig. 2—Effect of temperature and pressure in extruding free cutting copper alloy through a two-hole die 0.65 in. in dia.

The relative ease of extrusion of these alloys is approximately in the order listed, the first being the most readily worked.

Alloys 2S and 3S are subject to strain hardening only and can, therefore, be produced only in the annealed or as extruded tempers. The remaining alloys can be produced in the same two tempers and in addition, heat treated tempers. In all cases the extrusion temperature ranges from about 700-950°F. and velocities varying from about 5-300 ft. per min., depending on the size, shape and alloy.

Even though the annealed and as-extruded tempers of the heat treatable alloys are commercially available, all of these except 53S are generally used only in the heat treated tempers in order to secure the maximum mechanical properties and maximum corrosion resistance. Alloy 53S has essentially the same corrosion resistance in all tempers.

The aluminum alloys are subject to the same extrusion defect as are the brasses.

Hot Extrusion of Magnesium-Base Alloys—The magnesium-base alloys are of relatively recent introduction but for certain applications have already gained fairly wide acceptance. Several of the magnesium-base alloys are commercially extruded, using equipment essentially the same as that for copper-base or aluminum-base alloys.

As a class, magnesium alloys are quite hot short as compared to other alloys already dealt with. Therefore, only a narrow range of temperature is permissible and the extrusion rate is low as compared to that employed in the brasses. Commercially, speeds of approximately 2-12 ft. per min. are used.

Normally the temperatures are maintained between 600-800°F. for any of the magnesium alloys, the higher temperature being best for producing thin sections and the lower temperature for relatively heavier sections. The physical properties are somewhat affected by temperature, being decidedly better at the low temperature due to greater grain refinement.

In Table IV are given the properties of four alloys which can be extruded commercially.

In most commercial work the temperature and speed of extrusion is such that the pressure on the metal during the extrusion is between 40,000 and 60,000 psi. The starting pressure is naturally somewhat higher than this and is greatly dependent on the temperature.

Table IV
Extruded Magnesium Alloys

Alloy	Aluminum	Manganese	Zinc	Magnesium	Approximate Tensile, Psi.	Approximate Elongation, % in 2 In.
A	8.0	0.2	Remainder	47,000	13
F	4.0	0.3	Remainder	40,000	16
J	6.5	0.2	0.75	Remainder	43,000	18
M	...	1.5	Remainder	42,000	7

These alloys are particularly useful where advantage can be taken of their extreme lightness. For parts that have to be stopped and started very rapidly, the low specific gravity of 1.8 typical of these extruded materials is decidedly advantageous. Another advantage is their excellent machinability.

Hot Extrusion of Zinc-Base Alloys—The hot extrusion of zinc and zinc alloys has not been commercialized to any large extent because of the expense of the process. The expense lies in the greater extrusion pressure necessary than with brass and aluminum and the lower extrusion speed caused by the tendency of zinc and zinc alloys to check and crack as the extrusion speed and consequently the temperature build up.

High grade zinc has been extruded at speeds up to 75 ft. per min. The extrusion pressure approached 100,000 psi. initially. This material had ultimate tensile strengths of 14,500-20,500 psi. and elongations in 2 in. sections of 5-26% depending upon impurity content.

The zinc alloys containing copper or copper and magnesium show strengths up to 32,000 psi. and elongations of 3-7%, but the extrusion speeds decrease to 12 ft. per min. on $\frac{1}{2}$ in. dia. rod and the extrusion pressures run up to 120,000 psi. In extruding these alloys, the billets must be preheated to 520-570°F. and the container to 660°F. in order to start the extrusion.

Hot Extrusion of Nickel Alloys and Stainless Steel—Considerable experimental work has been carried out on the high melting point alloys but only recently has any commercial application been made. There is at present one installation where stainless steel tubing is being produced in commercial quantities using a 2,000 ton press. There is another installation using a 600 ton vertical press now commercially extruding nickel, Monel metal, and similar alloys. The basic difficulty is that several of the outstanding properties of these alloys are precisely those which intensify the difficulties of extrusion. Their great mechanical strength at high temperature and considerable resistance to deformation particularly militate against their production by extrusion methods.

Of course, several copper-base alloys containing considerable amounts of nickel are regularly produced in quantities but these are not looked upon as nickel alloys, being referred to in the section on copper-base alloys.

Cold Extrusion—Hooker Process—In the Hooker process relatively heavy walled cup shaped blanks are extruded at high speeds, using ordinary crank presses instead of the usual extrusion press. This operation differs essentially from the hot extrusion in two important respects. First, the metal is invariably fed into the press at room temperature and there is little, if any, rise in temperature during the process. At least the temperature of the metal remains well below that of incipient recrystallization so that a hard worked structure and corresponding properties result. Second, the process is carried out at relatively high velocities and on relatively small masses of metal. The Hooker process is commercially applied to two classes of products; first, small arms cartridge cases, and second, small thin walled seamless tubes.

In Fig. 3 there are shown four steps in the making of a small brass cartridge case. The alloy used is high grade 70-30 or cartridge brass. The first two steps comprise a cut-and-draw and a redraw, each performed in the ordinary manner on a plunger press. The third and fourth operations illustrate the application of the Hooker process. The two sectional illustrations show the position of the tools and the metal just at the start of and near the finish of the application of the Hooker process. It will be seen that with the application of pressure by the shoulder of the punch,

the metal is made to flow (extruded) through the restricted annular space between the punch and the opening in the bottom of the die.

This process is well adapted in general to small tubular articles in copper or aluminum where a large number of the same size piece are to be made. For instance, in 70-30 brass cartridge cases, this procedure is justified in competition with the ordinary drawing procedure on runs of approximately 10-15 million pieces. In the making of these cartridge cases, extremely high tool pressures are encountered, naturally resulting in considerable wear on the dies and punches.

In the manufacture of copper tubes, the sizes which are found economical, run from about $\frac{1}{8}$ in. O. D. to approximately $\frac{3}{8}$ in. but as yet not in commercial production. The wall thicknesses usually will vary from 0.004 to about 0.010 in. Anything less than about 0.004 in. is not commercial as it causes excessive tool breakage, and tubes with wall thicknesses over 0.010 in. can be produced at less cost by other methods. The length extruded is usually about 8-12 in. and the maximum feasible length about 14 in.

Although any type of copper probably could be used, oxygen-free copper is the one actually most employed. This, of course, is a homogeneous soft material, well adapted to this operation.

In the sizes ordinarily made the actual velocity of extrusion is much higher than ever attained in the ordinary hot extrusion of either rod or tubes on hydraulic presses. The actual working stroke consumes but a small fraction of a second and velocities through the die as high as about 2000 ft. per min. are attained. This is so rapid that there is little temperature rise in the die and the material itself is heated only slightly. The metal is severely cold worked and quite high strengths are found in the finished tubes. These may run from about 50,000-60,000 psi. in copper.

The Hooker process also is used in making a considerable range of small seamless aluminum tubes. Like copper, the aluminum is severely cold worked in this process but the extruded tube may be softened by suitable annealing subsequent to the extrusion.

Impact Extrusion—This process is somewhat similar to the Hooker process but differs from it in some fundamental respects. Whereas in the Hooker process the metal is extruded ahead of the punch through an annular orifice between the die and the punch, the flow of metal in the impact process is in the reverse direction. Here a solid bottom die is used and a flat slug of metal in place of the cup shaped slug of the Hooker process. Here also the punch has no shoulder and when the pressure is applied by the end of the punch to the flat slug, the metal flows back up over the punch. This process is sometimes erroneously referred to as the Hooker process and also sometimes by the misleading term "cold drawing." The term "impact extrusion" seems to be the more logical one to use.

In the making of flat bottom cans or cups of all types, this process frequently competes with similar shells drawn from sheet metal. The relation between the lengths and diameters of the can largely determines which process is the more economical. Relatively shallow articles are cheaper to produce by drawing but with increasing length the advantage swings toward the impact extrusion process. The impact extrusion process is applied to the making of various aluminum articles.

Shells or cups up to approximately 10 in. in length are found well suited to this process. The diameters may vary $\frac{1}{2}$ in. to about 4 in., and the wall thicknesses from about 0.003 in. to about 0.045 in. In general the wall thickness is more or less in proportion to the diameter of the tube or cup.

This process is also applied to making an enormous quantity of collapsible tubes such as used for tooth paste, paint pigments, and shaving creams, using pure tin or lead or tin-lead alloys. The pure tin is required for foodstuffs or materials for human consumption, but the lead alloys are found suitable and are naturally less expensive for containers for other types of products.

A great deal of zinc is extruded by this process, using blanks from $\frac{1}{4}$ -2 in. dia. and $\frac{1}{16}$ - $\frac{3}{8}$ in. thick. The dia. of the slug or blank usually equals the outside dia. of the finished cup, and a sufficient thickness is used to provide the desired length

Fig. 3—Diagrammatic sketch showing the steps in making a small brass cartridge case by the Hooker process.

at required wall thickness. In the application of the process to zinc, it is desirable to start with metal having a random orientation or at least a structure such that the blank has no directional properties. Otherwise the tops would be uneven, resulting in distortion of the side walls and causing an excessive loss in trimming. It is customary with zinc to heat blanks to a temperature of 390-480°F. in order to reduce the pressure required. It has been found that with common zinc a pressure of 87,000 psi. is required at 300°F. and 40,000 psi. at 480°F.

Forging by the Blacksmith

By William Telfer*

When selecting the material of the correct dimensions, the blacksmith first must decide how the part is to be forged. One procedure would be to select stock a little larger than the largest dimension and obtain the smaller dimension by drawing down. If the forging is to be short, stock comparable with the smaller dimensions could be used, and the larger dimensions could be obtained by upsetting. In either case it would be correct procedure to figure the approximate cubic contents or weight of the finished forging before selecting the stock, and allow enough for squaring up the end, and for loss due to scaling. The loss due to scaling varies with the number of reheatings and with the atmosphere and temperature of heating.

Blacksmith Tools—The tools used at the anvil with hand hammers or sledge hammers are swages, fullers, set hammers, flatters, punches and chisels with tongs to hold the work. The swages, fullers, set hammers and flatters are usually made of 0.70-0.80% carbon steel, and the hot and cold chisels of 0.80-0.90% carbon steel. A 0.45-0.50% carbon steel could be used for the bottom fuller and swage which fit in the square hole of the anvil. Cast medium carbon steel or a good gray iron will answer the purpose for the swage block.

Fullers—When shoulders are required on both sides of the forging, it is worked between the top and bottom fullers, the top being struck with a sledge. The top fuller is often used alone to make depressions on one side of the forging as it lies flat on the anvil. The radius of the depression or fillet will determine the size of the fullers to be used. Fig. 1 shows a top and bottom fuller.

Swages—These tools (Fig. 2) are used for finishing round or semi round work at the anvil after it has been drawn nearly to size by the use of either the hand hammer, sledge, or power hammer.

The depth of the impression should be about one third the diameter of the part of the forging to be swaged, and the edges should be well rounded. If the bottom swage is made to come flush with one or both sides of the anvil, it will have a greater range of usefulness.

Set Hammer and Flatter—Both are used on flat surfaces, but if necessary to work on square shoulders or in depressions which are too small for the flatter, the set hammer usually answers the purpose. The set hammer and flatter are both shown in Fig. 3.

Cold Chisel—Some steels in the hot or cold worked condition can be notched all

*Instructor in the Working, Treating and Welding of Steel, University of Michigan, Ann Arbor, Mich.

Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steever, Chairman; R. W. Thompson, F. B. Foley, O. W. Ellis, H. M. Spears, W. E. Jominy, W. W. Criley, and J. H. Friedman.

or part way around by the use of this chisel and a sledge, and then broken by a sharp blow (Fig. 4).

Hot Chisel—This is much thinner than the cold chisel (Fig. 4), and is used on steel at increased temperatures. The cut is usually made all the way through.

Hardie—This tool should fit in the square hole in the anvil. It can be used on some steels both hot and cold. The metal is placed on the hardie and struck with a hand hammer (Fig. 4).

When belt, air or steam hammers are used the tools are somewhat similar to those used for sledge hammering but modified to permit their use with power hammers.

Power Hammer Swages—Swages are usually made of 0.45-0.50% carbon steel, and the shape is obtained by sinking hot either by the use of a round bar or some special shape. Most of the work done by swaging is round in cross section, but special shapes can be produced by the use of these tools. Where the forgings are of a large diameter, the top and bottom swages are usually not attached by spring handles because of the weight to be handled by the helper. Fig. 5 and 6 show the hammer swages.

Power Hammer Fuller—The hammer fuller shown in Fig. 7 is used for drawing short sections where the dies are too wide, and also for forging a taper. The rounded side of the fuller is used for breaking down or roughing, and the flat side could be called a "flatter" for finishing.

Power Hammer Cutters—Hot cutters (Fig. 8) usually consist of a straight blade with a handle about 3-8 ft. long depending on the size of the forging. Some are made with curved blades and others form an angle of 90°. The handle near the blade should be flat so as to act as a spring and prevent injury to the wrists or arms of the blacksmith.

Stocks—These are used for turning and handling the forgings at the hammer. Fig. 9 shows how they are used.

When the quantity of forgings of the same kind justify the making of dies, the blacksmith first makes one forging, taking special care with the shape and dimensions. This sample or master forging then is made use of to sink the die or dies. The die blanks are usually forged with handles drawn out. The next step would be to heat the blanks to a high temperature, and put the master in between, and then force them together by the use of heavy blows. Sometimes the dies are partly sunk before using the master forging. These dies or swages, as they are sometimes called, are held in line by spring handles or guide pins, or both, and held on the bottom hammer die by the helper. The smith has used this method of increasing production for many years. It has been used for some time, but on a much larger scale, by the producers of drop forgings.

Forge Fire—A cast iron hearth with a bowl or depression in the center for the fire, and an opening in the bottom for the tuyeres will answer the purpose for light work. For heavy work an inexpensive forge can be constructed from $\frac{1}{2}$ in. steel plate formed into a square or a cylinder about 4 ft. in dia. and 2 ft. 6 in. in height. Space below the tuyere can be filled with broken brick and ashes. The distance between the top of the hearth and the tuyere should be about 10 in. for heavy, and about 4 in. for light work. Provisions should be made for removing ashes from below the tuyere. The clinkers can be removed from above. After starting the fire, wet coal is banked on both sides, this not only supplies coke for surrounding the metal to be heated, but acts somewhat like the fire brick wall of a furnace.

The object is to heat the steel uniformly to high temperature with as little oxidation as possible. This can be accomplished by keeping a good bed of coke between the tuyere and the steel to consume the oxygen in the blast, and a good covering is necessary. Better control of the atmosphere and the temperature can be obtained in a furnace, but in a forge fire, the heat can be concentrated at some given point of the bar or forging.

On building a forge fire for medium and heavy work, a block of wood corresponding to the size of the fire required is placed on the tuyere, and wet coal is firmly packed around it to the depth required. Two boards are then used as forms to build the banks to the length and height required.

The fire is started by shoveling hot coke into the hole left after the wood is removed. The banks usually stand undisturbed for a half to a whole day, and hard coke broken to a convenient size is used as a fuel.

The banks of coal coke to the depth of several inches during the day and this coke is used along with the hard coke on the following day, after the fire is rebuilt.

Fine coal is more desirable for forge fires, as it packs much better when wet than coal consisting of lumps. A good grade of bituminous coal, low in ash and sulphur, high in fixed carbon, and good coking qualities, is usually the fuel for the forge.

Hammer Size—During the forging of the steel, the size will determine the method of applying the force. If the temperature is close to the upper limit of the plastic range, a 1½ lb. hammer would supply enough force for ¾ in. dia. low carbon and ½ in. high carbon steel, and a 14 lb. sledge would answer the purpose up to 1½ in. low carbon steel. Of course, if the smith has access to a power hammer, time would be saved by using it.

Precautions in Heating and Forging Steel—Too rapid heating will cause uneven expansion of the metal, starting internal cracks. This is especially dangerous in high-carbon and high-alloy steels. When such steels have to be heated near the upper limit of the plastic range, it would be advisable to use a preheat furnace at temperatures between 1,200 and 1,400°F., depending upon the composition, size, and previous treatment.

Forging temperatures too high for the amount of work to be done will result in large grains in the finished forging. Excessively high temperatures used might be in the melting range, and when forged, will cause voids and oxide inclusions. This is commonly called burning.

Not enough force applied will cause a rupturing of the steel by working the outer layers beyond the inside metal. Sufficient force should be applied to affect the whole cross section, and this should be continued until close to the finished forging dimensions.

Continuing the forging at temperatures too low will leave the steel in a highly stressed state, and, if not followed by some form of heat treatment, will result in short life for the machine part.

When a great reduction in size is necessary, the steel should be forged down on the square or rectangular shape. The stock should be turned so that the sides will form an angle of 90°. If the finished cross section is to be round, forging should be continued on the square until close to the finished dimension. The corners can then be forged to produce an octagonal shape, and little rolling is necessary to finish.

If the above procedure is not carried out, the metal might be in shear some of the time, instead of compression, and if the steel is slightly rigid due to low temperatures or a hard alloy steel, such as high speed steel, it will be ruptured.

Overlapping of the steel, forming cold shuts, is often caused by using hammer dies and tools with sharp corners.

The above applies to both forging on the anvil using a hand hammer and forging between the flat dies of a power hammer or press.

Welding at the Forge—When wrought iron or steel is heated to high temperatures, such as used in welding, and are exposed to the air, they oxidize rapidly. To secure a good bond between two pieces, this oxide must be so fluid that it can be squeezed out from between the surfaces. The fusion point of the oxide is lowered by the use of fluxes.

Clean silica sand and borax are two common fluxes used at the forge. Borax, having a comparatively low fusion point, is used on high carbon steel. It can be placed on the steel at low temperatures, after "scarfing," consequently supplying a protective coating. Also, it can be sprinkled on the steel while heating. It might be said it serves a double purpose, lowering the fusion point of the oxide, and preventing further oxidation.

Sand has a high fusion temperature, but when combined with iron oxide it becomes fusible at lower temperatures. It is generally sprinkled on the metal when close to the welding temperature.

Silica sand is cheaper than borax and can be used on the low carbon steels. Fluxes are not necessary in forge welding of wrought iron and very low carbon steel, because it is possible to melt the oxide without burning or melting the metal.

The operation of preparing the pieces for welding is known as "scarfing." Fig. 10 shows the shape used in lap welding. Other types of welds are known as butt, V or split, T, corner, and jump.

Precautions in Forge Welding—Before shaping the "scarfs" upset the end of the pieces to be welded sufficiently, and far enough back from the "scarf" to allow for enough mechanical working during and after welding.

The grain size of the metal in the weld and adjacent to the weld will depend on the amount of work it receives and the finishing temperature.

The "scarf" surfaces should be well rounded so that contact will be made in the center. The curved surfaces will force the liquid oxide or dirt out from between.

Guard against excessive oxidation on heating by keeping a good supply of coke in the bottom of the fire, and have the metal well covered with fuel. The scarfed ends should be face down in the fire.

When up to the welding temperature, enough speed should be used to get the pieces together before the oxide solidifies.

Blows should be heavy enough to work the metal uniformly, using a power hammer when necessary.

The metal in and adjacent to the weld may be annealed to produce a more homogeneous structure, and consequently obtain greater ductility, which usually is low in forge welds.

The properties of a forge weld will depend on the following factors: (1) The skill of the welder; (2) The weldability of the material; (3) The fuel used—sulphur and ash will interfere; (4) The amount of flux used and the time of application; (5) Uniformity of temperatures of pieces to be welded; (6) Atmospheric condition of the fire or furnace; (7) Amount of oxide or fuel ash trapped in between the "scarfs"; (8) Method of working—too much rolling on the anvil or between the dies of a power hammer when welding round stock will be detrimental, and (9) Force of the blow.

Straightening Bars, Shapes and Tubing

By J. D. Armour*

Many types of straightening devices have been developed for straightening bars, shapes and tubes from the simple hand straightening to very complicated straightening machines. However, the fundamental principle involved in all of these straightening methods except twisting and straightening by stretching is the same. This principle may be explained by referring to Fig. 3. The bar is supported at points A and B with the convex side of the bow or kink toward point C. Sufficient pressure is applied at C to cause the bar to become bowed in the opposite direction. The pressure must be sufficient to exceed the elastic limit of the material and set up just sufficient strain in the bar to allow it to return to the straight position but

no farther when the pressure is released. The greater the bow in the bar and the higher its elastic limit the greater the pressure required to produce the correct amount of strain. To straighten a bar by this method, the material must possess the property of resilience, it must be capable of cold deformation, and it must strain harden. In the diagrams, Fig. 2-10 inclusive, the arrows show the location of the points corresponding to points A, B and C of Fig. 3. As mentioned above, this same principle applies in all of the bar straightening methods except twisting and straightening by stretching.

In straightening to remove twist, the bar is twisted in the opposite direction until the elastic limit is exceeded and just sufficient strain set up to allow the bar to return to the straight position but no farther.

In straightening by stretching, the bar must be stretched until the elastic limit is exceeded and sufficient strain set up to prevent the bar from returning to its original position. The bar must be permanently elongated and reduced in cross section to remain straight after the stress is removed.

Hand Straightening—While many mechanical methods have been developed for straightening bars and shapes, the original method of hand straightening is still used extensively on jobs where great accuracy and precision are required or where odd shapes make mechanical straightening impractical.

For accuracy and precision, surface tables and wooden mallets are used while, for odd shapes, grooved wooden blocks as illustrated in Fig. 1 and 2 are used. Hand straightening requires great skill on the part of the operator and it sometimes requires several years for an operator to acquire sufficient skill to do particular jobs of hand straightening.

Punch and Press Straightening—Punch and press straightening are semimechanical methods, the principle of which is illustrated in Fig. 3. The operator usually locates a kink or bow in round bars by holding a piece of chalk close to the surface of the bar and then rotating the bar so that any high spots will be marked by the chalk. The high spot is then brought under the ram of the straightening press and sufficient pressure applied to take out the kink or bow. In the case of shapes other than rounds, the out-of-straight condition must be detected by eye or with the aid of a straight edge. The type of straightening requires considerable skill on the part of the operator. A straightening press is sometimes referred to as a gag press and the straightening operation as "gagging."

Rotary Straightening—Rotary straighteners are straighteners in which the bar is rotated at the same time it is fed into the straightening machine and are necessarily confined to straightening round bars. The simplest form of rotary straightener is illustrated in Fig. 4. The top roll can be set at any desired angle which controls the speed of the bar. It can also be adjusted up and down to control the pressure of the bar. It can readily be seen by referring to Fig. 4 that the same principle of straightening is involved here as for punch or press straightening.

Fig. 5, 6 and 7 show diagrammatically other popular types of rotary straightening machines. While they are more complicated in design than the simple rotary straightener to obtain such features as speed or polishing effect, they nevertheless involve the same straightening principle as can readily be seen by a little study of the illustration.

Fig. 8 illustrates the principle of a straightening machine used for flats, squares and hexagons. It will be seen that as the bar passes through the machine it is subjected to a double straightening action similar to that employed in Fig. 3. In some straighteners for these shapes, both horizontal and vertical rolls are used which give a setup similar to that shown in Fig. 10 for wire.

Wire Straightening—Fig. 9 shows the type of straightening machine used for straightening coiled round wire into straight bars. In this case, the wire does not rotate as it feeds through the machine. A cylinder with adjustable dies rotates around the wire and produces the straightening action. Some straightening is also provided by the feed rolls on the entering end as will be seen from the illustration.

Fig. 10 illustrates the setup for a wire straightener for shapes other than rounds. It amounts to a double setup similar to Fig. 8, one horizontal and one vertical, so that the wire will be straightened in both directions with one pass through the machine.

Stretching—Fig. 11 shows how a bar must be changed in size to be straightened by stretching. The change of shape is of necessity exaggerated in the illustration as the increase in length and decrease in cross section need actually be very slight to produce the required effect. This method is well adapted to straightening odd shapes.

Flattening of Mild Steel Sheet and Strip

By R. S. Burns*

Sheets are ordinarily sold in two grades of flatness: (1) commercial flatness, in which the sheets are to be severely drawn, and hence, the original flatness does not have much effect on the shape of the drawn article; and (2) stretcher level flatness, in which the sheets are used for panel work where little forming is done on the sheet, and the finished product is desired flat and free from buckles.

Simply because sheets are flat before moderate forming does not necessarily mean that they will be flat after fabrication, unless care is taken by the fabricator to insure that buckles are not thrown into the sheets during forming.

Commercial flatness can ordinarily be produced on a roller leveler or cold rolls, but where it is required that sheets be very flat, producers must resort to stretcher leveling. For the most part, steel sheets are flattened as a final operation before shipping; however, there are instances where measures are taken to flatten sheets as an intermediate operation, in which case the flattening is done both to improve the flatness of the finished product and also to aid in the performance of succeeding operations.

The normal flatness varies somewhat according to the grade; and as a rule the lighter the gage and the wider the sheet, the less flat the sheets will naturally run.

The permissible variations in flatness for commercial cold rolled and stretcher leveled sheets as set up by the Association of American Steel Manufacturers Technical Committees are as follows:

Ordered Gage (U.S.S. Ga. No.)	Ordered Width, in.	Max. Height of Buckles, in.
2 to 11, incl.....	48 or under	$\frac{3}{8}$
	Over 48 to 60 incl.	$\frac{3}{4}$
	Over 60 to 72 incl.	1
	Over 72	$1\frac{1}{4}$
12 to 16, incl.....	48 or under	$\frac{3}{8}$
	Over 48 to 60 incl.	1
	Over 60 to 72 incl.	$1\frac{1}{4}$
	Over 72	$1\frac{1}{2}$
17 to 30, incl.....	36 or under	$\frac{3}{8}$
	Over 36 to 48 incl.	1
	Over 48 to 60 incl.	$1\frac{1}{4}$
	Over 60	$1\frac{1}{2}$

For stretcher leveled sheets, 22 gage or heavier, the height of buckles of a sheet lying on a flat surface shall not exceed $\frac{1}{4}$ in. This permissible variation cannot be assured for sheets lighter than 22 gage.

The permissible maximum height of buckles given for stretcher leveled sheets and for sheets not stretcher leveled applies to not more than two buckles on a side or in the middle of the sheet.

Roller Leveling—A roller leveling machine consists of two sets of several horizontal small diameter rolls held in a housing and so arranged that the top and bottom rows are offset, permitting the rollers to mesh. The upper and lower rolls are so staggered or meshed that the sheet passing through the leveler is flexed alternately up and down (Fig. 1). This has the effect of cold working the surfaces more than the interior of the sheet. The layers of rollers are movable with respect to each other; so that by means of a screwdown the rollers may be made to mesh more or less as desired, thus controlling the pressure exerted on the piece during the operation. On levelers with the proper amount of staggering of the rolls, flatness may be obtained with essentially no increase in length of the sheet. At the entrance side of the leveler, the axes of the bottom and top rolls are closer together than at the exit side. This results in heavier flexing in passing through the earlier rolls of the machine. At the exit side the action is chiefly that of straightening. Sheets are ordinarily passed through the roller leveler one at a time; however, in some cases several may be passed through at a time, depending on the thickness.

Hot roller leveling is usually a part of the treatment for hot rolled sheets and plates over .060 in. in thickness. This has the effect of removing much of the distortion caused by hot rolling and open annealing. When roller leveling hot, it is not necessary to temper pass material before leveling to prevent breaks or fluting.

*Research Engineer, The American Rolling Mill Co., Middletown, Ohio.

However, before it is possible to cold roller level a dead soft annealed sheet, the sheet must receive a pass on the temper mill to minimize the yield point elongation, and hence, prevent "roller level breaks" or fluting as the sheet is bent around the rolls.

With the advent of wider and thinner cold rolled sheets, roller leveler manufacturers have resorted to machines with small roll diameter. To get the same amount of stress in the extreme fibers of a sheet, it is necessary to bend the lighter gage sheet around a smaller diameter roll. With the use of small diameter rolls in the leveler, it has become necessary to back the rolls up with rolls of larger diameter to decrease the flexing of the roll when pressure is applied. Then, too, with the recent developments in high tensile steels, it has been found that these sheets cannot be flattened on the ordinary leveler but must be run on the leveler with small rolls in order to create a stress high enough to get the necessary deformation. Roller levelers are not ordinarily used to eliminate the tendency to stretcher strain unless the sheet has first been temper rolled. Sometimes if the sheets are unused for a period long enough to cause an appreciable return of the yield point of elongation due to aging, the tendency of the sheet to stretcher strain may be eliminated, for a short time, by roller leveling immediately before drawing. In this case the roller leveling is not done as a flattening operation but is done to prevent stretcher strain during drawing.

Roller level corrugations or chatter, consisting of small waves running across the sheet, constitute the main defect caused by this operation. Ordinarily this defect occurs because the leveler is not properly adjusted for the gage of the sheet being leveled, or when the sheets are badly buckled before roller leveling takes place. Roller leveling is only a semieffectual means for flattening sheets, and sheets having a full center are easier to flatten by roller leveling than sheets with long or wavy edges. It is a relatively inexpensive operation, and sheets of commercial flatness can readily be produced.

Roller level corrugations or chatter, consisting of small waves running across the sheet, constitute the main defect caused by this operation. Ordinarily this defect occurs because the leveler is not properly adjusted for the gage of the sheet being leveled, or when the sheets are badly buckled before roller leveling takes place. Roller leveling is only a semieffectual means for flattening sheets, and sheets having a full center are easier to flatten by roller leveling than sheets with long or wavy edges. It is a relatively inexpensive operation, and sheets of commercial flatness can readily be produced.

Stretcher Leveling—Stretcher leveling is a positive means of producing flatness in finished sheets, if the sheets have been properly processed for good flatness in stretcher leveled sheets. In this operation sheets are gripped on each end by jaws attached to pistons which are forced apart slowly by hydraulic pressure (Fig. 2). The number of sheets stretched at one time depends on the gage. However, it is rare that more than two sheets are stretched at one time, because the grips do not hold tightly enough to stretch the center sheets. The effect produced is actually one of stretching the sheet gradually, taking up all the slack which may exist in the form of waves or buckles, continuing until the sheet is stretched taut and its shape is practically a flat plane. The stretching proceeds, theoretically, past the elastic limit of the steel, being in the neighborhood of 1-2% elongation, so that the sheet will not spring back into its original shape but will spring back uniformly across its full width and remain flat. This means that the sheet takes a permanent set in its flat condition, which shape is not materially altered when stretching is stopped and the sheet is removed from the grips.

For stretcher leveling, it is obvious that sheets must be soft and ductile and have an elastic limit low enough to permit them to take a permanent set with a pull which is within the limit of the stretching machine. Dead soft sheets are not usually stretcher leveled without first giving them a temper pass on the cold mill. Unless sheets are given a temper pass prior to stretcher leveling they have a

Fig. 1

Fig. 2

Fig. 1—Diagrammatic sketch of a roller leveler.

Fig. 2—Diagrammatic sketch of a stretcher leveler.

tendency to stretcher strain when stretcher leveled and even if the stretching proceeds far enough to pull through the stretcher strain, strain markings are left on the sheet and are undesirable for many applications.

Material that has a variation in physical properties across the sheet usually does not stretcher level satisfactorily. The differences in unit stress produce variation in strain, within the elastic range, across the sheet, with the result that release of the load produces different amounts of elastic contraction which causes nonflatness.

Nonuniformity in gage across a sheet of material frequently gives trouble in stretcher leveling. This is due to difficulties in obtaining perfect gripping. Slippage in the grips will produce different unit stresses in different parts of the sheet. If this slippage is high enough so that stretching is not carried definitely beyond the yield point in all parts of the material, varying amounts of elastic contraction will result upon release of load, which in turn produces nonflatness.

As the physical properties of sheet material increase, the leveling operation becomes more difficult because of the greater elastic contraction upon release of load, as well as greater difficulties in obtaining perfect gripping in the leveler.

In stretcher leveling light gage sheets (.031 in. and thinner) the difficulties are greatly increased, owing to inability to elongate the sheets sufficiently to flatten them without producing cross breaks or buckles parallel to the direction of stretch.

Cold Drawing Steel Wire

By E. E. Legge*

Wire is ordinarily thought of as consisting of long circular sections. Yet it may have any one of an infinite number of cross sectional shapes. The most common shapes are circular, square, hexagonal, octagonal, oval, half-oval, half-circular, triangular, and flat or rectangular. In general, wire consists of innumerable products shaped by pulling metal through a die.

The limits of wire drawing range from .001 in. to approximately 1 in. Wire is classified with respect to size as coarse wire—coarser than No. 20 (.035) gage—and fine wire (No. 20 gage and finer).

Historical—Iron wire was first manufactured in Bavaria, in the middle of the fifteenth century. In America, the first steel wire was drawn by Nathaniel Miles, in 1775. Later, in 1831, Ichabod Washburn and Benjamin Goddard drew steel wire in Northville, now Worcester, Mass.

General Description of Process—The process of drawing steel wire begins with a hot rolled rod in coil form, weighing from one hundred to six hundred pounds, depending upon the type of rod mill used and the quality of rod surface desired.

The wire requirements determine whether Bessemer, acid or basic open hearth, or electric steel should be used. Special alloying elements are rarely used except for the larger sizes of wire because alloys are not required in small sections to produce a uniform heat treatment throughout the entire cross section. Combinations of cold working and heat treating of rods and process wire make it possible to develop a wide range of physical properties which will meet almost every demand likely to be made upon steel wire.

The range of analysis of plain carbon steel is carbon 0.05-1.30%, manganese 0.15-1.65% with the other elements normal for the type of steel.

Most wire is drawn dry, with adequate lubricants; however, fine sizes and special finishes are drawn by the so-called wet process. Neither of these processes involves any change in the actual operation of drawing, but in the preparation of the wire for drawing, they differ widely.

In dry drawing, the wire is cleaned with acid, coated (usually with lime), baked, and drawn dry through a lubricant in the die box. The wire is first pointed by suitable means and then pulled through the die with tongs until sufficient wire is available to attach to the wire drawing block (Fig. 1). When this block revolves, it coils the wire about itself, continuously draws the wire through the die, and brings about the fixed decrease in sectional area.

In wet drawing, the wire, after acid cleaning, is immersed in a dilute solution of copper or tin sulphate, or a mixture of both, depending upon the color desired. The coils are then removed and placed in a vat of fermented liquor made from rye meal and yeast from which they are drawn wet, with the liquor serving as a lubricant.

Cleaning and Baking—The cleaning of hot rolled rods before the wire drawing is the basis for success or failure in the production of good wire. Roll scale, if left on the rods, will not only reduce the life of the wire drawing dies but will cause scratches and surface imperfections that never draw out. Overcleaning with pitting will produce rough surfaces. Muriatic acid is sometimes used, but a hot (185°F.)

Fig. 1—Wire drawing block.

*District Director of Research, American Steel & Wire Co., Worcester, Mass.

solution of sulphuric acid is more commonly used for cleaning or "pickling." Acidity of the cleaning solution and time of immersion are regulated according to the analysis and the type of steel being cleaned. High carbon steels are cleaned in stronger acid solutions and for relatively shorter periods of time; low carbon steels, in the lower acidities, for longer periods of time. Low carbon basic steels require stronger acid than Bessemer steels. Inhibitors should be used to prevent excess waste of steel and acid; also to prevent pitting and excessive fuming.

Wire rods, after being cleaned in acid, are rinsed in cold water and washed with a high pressure hose. Usually they are then dipped into a vat of lime emulsion for coating, although they may be dipped in copper sulphate or be given a sull coating (a brownish wet rust produced by water spraying after acid cleaning) before the lime dip, if it is so desired. Lime emulsion is used either cold (120°F.), or hot (180°F.). Cold lime, when used, has a concentration of 3-5%. Hot lime is used in the following concentrations: light 3-5%, medium 6-9%, heavy 10-12%, extra heavy 12-15%. The larger the number of drafts, the heavier the lime coating. The limed rods are baked at a suitable temperature for a period of time sufficient to dry thoroughly and to remove acid brittleness.

Drawing—Dies—While chilled cast iron, cast chromium steel, and forged steel dies are still used, tungsten carbide dies are rapidly displacing them. Diamond dies are still preferred on very small sizes of 0.010 in. dia. and under, up to 0.025 in. dia. for finishing drafts. Because of limited production of "shape" wire, hardened punched chromium steel dies are employed.

Machines—Wire drawing is usually accomplished by means of an equipment known as a wire drawing frame. Each frame is composed of a bench with several wire drawing blocks. Fig. 1 shows one block of such a section, with the die box, die holder, and the draw-out mechanism for drawing the first few feet of wire through the die. Frames are usually referred to as "rod frames" and "wire frames," according to the use to which they are put.

Bull Blocks are used for very large sizes of wire up to $\frac{1}{2}$ in. dia. This equipment is a large single block, built for tremendous strength and power. On such equipment, rods are usually drawn one draft with $\frac{1}{2}$ - $\frac{3}{4}$ in. reduction.

Draw Benches are used for the large sizes of rounds and shapes which are later to be straightened and cut to length. See the article on Cold Finished Carbon Steel Bars and Shapes.

Double and triple deck wire drawing blocks are so arranged that two and three drafts may be drawn at the same time by a special arrangement of die holders with respect to the two or three elevations of blocks.

Continuous dry drawing machines are used for successively drawing several drafts by suitable equalizing of the successive speeds from one block to the other, or by arranging storage capacity on each succeeding block to make up for the net increase of wire at each stage.

Continuous machines for wet drawing fine wire are used from 4-13 successive drafts. They generally consist of cone-like wire drawing blocks, so designed that the steps of the "cone" accommodate the increase in the length of wire with a minimum of slippage. The lubricant is forced in a stream to the dies in some types, while in others the dies are immersed in the lubricant.

Lubricants—A large variety of drawing lubricants are used, depending on the number of drafts and the finish desired. The most common lubricants are:

Grease, used for one to three draft wire;

Soap, used for one to six draft wire;

Liquor, used for wet drawing, made from water and rye meal flour which is allowed to ferment. The metallic coating of copper, or copper and tin, requires no other lubricant than this liquor; but the percentage of reduction per draft must be less than in the case of dry drawing.

Reductions—The per cent reduction of area per draft is figured thus:

$$\% \text{ reduction of area} = \frac{100 (S-s)}{S}$$

Where S equals area of original section and s final section.

Low and medium carbon wires are reduced 40% and less per draft, whereas higher carbons are reduced only 30% and less per draft. Wet drawn wires are reduced only 18% and less per draft.

Process Heat Treatments—In order to obtain the desired properties for certain

Fig. 2—"A" hard drawn structure before annealing, C 0.09%, X 250. "B" structure after annealing "A," X 250. "C" spheroidized structure, C 0.98%, X 1000. "D" structure after air patented, C 0.70 and mn. 0.73%, X 1000. "E" same steel as in "D" after lead patented, X 1000.

wires, the rods or process wire are given a heat treatment to develop the proper microstructure.

For low carbons, the most common heat treatment is annealing at temperatures in the vicinity of, or slightly lower than, the critical range.

Fig. 3—Increase in tensile strength with increase in reduction.

Fig. 4

Fig. 4—Effect of reduction on elongation. The carbon content varying from 0.05-1.00%

Process annealing recrystallizes the ferrite so that further drafting may proceed to finer sizes. Fig. 2A shows a hard-drawn structure before such an annealing. Fig. 2B shows a structure after annealing.

Medium and high carbon steels are sometimes spheroidized, when soft wire is

required, or when this structure is desired before a final heat treatment (Fig. 2C). Medium and high carbon steels are more frequently patented either in air or in lead to give a fine pearlitic structure, often referred to as "sorbite," in order to obtain a high initial strength and the best characteristics to permit drawing to high tensile strengths. (Fig. 2D, air patented, and Fig. 2E, lead patented.)

Finishes—Many of the finishes are the natural result of the coatings and lubricants used in the wire drawing practices. Others are the result of special coatings added to the wire after drawing. The more common finishes are designated as black, bright, black annealed, bright annealed, liquor finish, coppered, tinned, and galvanized.

Coils and Straightened and Cut Lengths—The following coil sizes are employed, with the approximate wire sizes:

Size	Dia. of Coil
0.027 in. and finer	8 in. coils or spools
0.028-0.073 in.	12 or 16 in. coils
0.074-0.375 in.	22 in. coils
0.375-0.687 in.	26 or 28 in. coils
Coarser than 0.687 in.	Straight and cut to length

If desired, all sizes may be straightened and cut to specified lengths, bundled and burlapped, or boxed.

Physical Properties—Regardless of the initial tensile strength of a low, medium, or high carbon steel in the green, annealed, or patented condition, the gain in tensile strength, owing to increased drafting, follows a reasonably definite trend as shown by Fig. 3. The elongation also follows a definite trend, and the losses are shown in Fig. 4. The physical properties of typical medium carbon steel are shown in Fig. 5 as the percentage of drafting increases.

Fig. 5—Effect of reduction by cold drawing on the properties of carbon steel. Initial size of rod was 0.304 in. dia. The initial condition was OF Patented

Cold Finished Carbon Steel Bars and Shafting

By H. W. Graham*

Definition and Application—The cold finishing of steel, generally used for bars and shafting, may be defined as the process of reducing their cross sectional area, without any heating, by one of five methods:

1. Cold rolling; 2. Cold drawing; 3. Cold drawing and grinding; 4. Turning and polishing; and 5. Turning and grinding.

Cold finishing is employed principally for one or more of the following reasons: (a) Special size accuracy; (b) smooth or bright surface finish; (c) improved physical properties; and (d) better machinability.

The selection of the method to be used is governed either by economic reasons, section, or the necessity to meet requirements characteristic for one of the methods. For example, the usual practice is to cold draw the smaller sizes of rounds up to about 3½ in. and turn the larger sizes. Whenever a superior finish or size accuracy is required the material is ground. Turned and polished bars, usually over 1½ in., are furnished where hot rolled physical properties and cold finished size accuracy are desired plus a finish that is reasonably free from the normal surface imperfections of hot rolled bars.

Historical—Cold finishing first appeared in 1859, as a cold rolling process for wrought iron, invented and patented by Bernard Lauth. Later, the same process was used on steel, primarily for shafting for power transmission units, machinery, and agricultural implements.

Cold rolling, as a means of cold finishing, gradually lost ground after developments in the wire industry disclosed that drawing the larger wire sizes through dies produced practically the same improved physical properties. Finally, in about 1890, the two processes were considered interchangeable from the standpoint of effect, and although cold rolling was never replaced completely, and is still used for certain purposes, such as wide flats, the principal method of producing cold finished steel today is by cold drawing.

The growth of the cold finished industry during the past thirty years is largely attributed to the demands for the cold finished product that accompanied the rapid development of the automotive, electrical equipment, and machinery industries. The producers of cold finished steels have kept pace with the progress of these industries by providing a variation of standard and special analyses, finishes, and treatments in order to satisfy a diversified range of requirements.

Description of Cold Finishing Processes—General—Since the surface defects and imperfections present in the hot rolled product are accentuated by cold drawing, it is necessary that the preparation of the hot rolled material for this purpose be surrounded with precautions to assure the proper cold finished surface quality, size and finish. In fact, the surface requirements of hot rolled bars for cold finishing purposes are similar to those practiced for forging steel; that is, the surface must be substantially free from seams, pits, and excessive scale.

Prior to cold drawing, the hot rolled material is usually immersed in a bath of 4-8% sulphuric acid, at a temperature of about 150°F. until the scale is completely removed. It is then washed and dipped in a lime solution which neutralizes any acid that may be remaining on the bars, and also serves as a rust preventive and a lubricant in the finishing. Drawing through a die, straightening, and then cutting to length complete the sequence of operations.

Fig. 1—Typical stress-strain diagrams of hot rolled and cold drawn steels.

*General Metallurgist, Jones & Laughlin Steel Corp., Pittsburgh.

Cold Rolling—Cold finishing by cold rolling involves passing the hot rolled bars, cleaned of scale, repeatedly through a set of rolls, thereby subjecting the material to a light reduction in each pass, until the final size is obtained. Cold rolling imparts a bright surface finish, accurate size, and an appreciable increase in the tensile strength with an even greater increase in the yield point.

Cold Drawing—In this method, a hot rolled bar of practically any shape, after having been cleaned of scale, is pulled cold through a die whose bore section is generally $\frac{1}{16}$ - $\frac{1}{8}$ in. smaller than the hot rolled dimension or thickness. The amount of draft, however, may be varied from $\frac{1}{16}$ - $\frac{1}{4}$ in., depending upon the analysis of the material being drawn, the hot rolled size, and the physical properties desired. The effects of cold drawing are similar to cold rolling, the final product having a bright surface finish, accurate size with its tensile strength and, particularly the yield point, materially increased.

Cold Drawing and Grinding—For purposes where the size accuracy, surface finish, straightness or concentricity imparted by cold drawing, or turning and polishing are inadequate, grinding after cold drawing is resorted to. The physical properties of this type of cold finished product remain unchanged from those of the cold drawn bar.

Turning and Polishing—Whereas cold drawing reduces the cross sectional area by subjecting the bar to compressive and elongating forces, turning and polishing accomplishes the same by turning a $\frac{1}{16}$ - $\frac{1}{8}$ in. from the diameter, depending on the bar size, usually followed by polishing and straightening in a combination straightening and polishing machine. By this method, close size accuracy is obtained, similar in degree to that of cold drawing, but the finish of the surface is somewhat brighter, and surface decarburization, surface seams, and other minor hot rolled defects which are not affected by the cold drawing operation are removed. Since the steel has not been cold worked in any appreciable manner, the physical properties of the hot rolled bar follow through to the turned and polished product.

Turning and Grinding—In this process, after the hot rolled bar has its rough and imperfect surface removed by turning, it is ground, usually in the centerless type of machine, resulting in a product whose finish and characteristics are similar to cold drawn and ground material, except that the hot rolled physical properties have not been changed.

Size and Finish—From the above discussion, the various methods of cold finishing may be grouped as follows according to superiority of size and finish:

Size Accuracy	Finish
First—Turning and grinding or cold drawing and grinding.	Turning and grinding or cold drawing and grinding.
Second—Turning and polishing or cold drawing.	Turning and polishing.
Third—Cold rolling.	Cold drawing or cold rolling.

One of the outstanding advantages of cold finished steel is the close size tolerance that can be maintained. Cold finished bars are straightened commercially within $\frac{1}{32}$ of an in. in 5 ft. Rounds for shafting purposes are held considerably closer, and even better straightness requirements can be met by special processing in straightening.

Physical Properties—Table I gives average physical properties of cold drawing, hot rolled bars of the various analyses listed. The data presented are general in nature, and should therefore not be interpreted as values necessarily obtainable in all cases, sizes, and conditions. Also the stress strain diagrams in Fig. 1 give a general idea of the marked increase in tensile strength and particularly yield point that occurs in this process. The tensile strength is not raised as much as the yield point, but since permanent distortion is a function of the yield point rather than of the tensile strength, this effect upon cold drawn materials is of vital importance in applications in machinery.

The increase in yield point is accompanied by a decrease in elongation and reduction in area, but not enough to materially interfere with the use of such materials where the higher yield points are necessary. A cold drawn bar of properties intermediate between the extremes in yield point and elongation can be obtained by annealing or normalizing treatments.

Because of its desirable physical properties, cold drawn bar stock is often applied in substitution for heat treated bars, since it is not as costly, and is easier to machine. Also, in applications where it is desired to have heat treated properties

Table I
Average Physical Properties of Cold Drawn Steel
Sizes $\frac{1}{2}$ -2 in. Dia. Test Specimens 2 \times 0.505 in.

S.A.E. Steels	Tensile Strength	Yield Point	Elongation in 2 in., %	Red. of Area, %	Brinell Hardness No.
1010	67,000	55,000	25.0	57.0	137
1015	71,000	60,300	22.0	55.0	149
1020	75,000	63,700	20.0	52.0	156
1025	80,000	68,000	18.5	50.0	163
1030	87,000	73,900	17.5	48.0	179
1035	92,000	78,200	17.0	45.0	187
1040	97,000	82,400	16.0	40.0	197
1045	102,000	86,700	15.0	35.0	207
1112	87,000	73,900	17.0	45.0	183
1120	78,000	66,300	19.5	49.0	159
X1314	80,000	68,000	19.0	51.0	163
X1315	82,500	70,100	18.5	50.0	167
X1330	98,000	83,300	18.0	40.0	201
X1335	105,000	89,200	16.0	35.0	217
X1340	112,000	95,200	14.0	30.0	223

along with the more accurate size tolerances, hot rolled bars may be heat treated in accordance with the requirements and then turned and ground, or turned and polished.

Of late, some attention is being given to the effect of strain drawing cold drawn bars at temperatures in the neighborhood of 500 and 600°F. Such low temperature treatments have practically no deleterious effect on the close size or smooth finish of the cold drawn bar, and are instrumental in boosting the tensile strength and yield point without sacrificing ductility. This phenomenon is of value for further increasing the strength of cold drawn steel.

Machinability—Another important advantage of cold finished materials is its superior machinability as compared with a hot rolled product. This superiority depends upon several features including an improved machining quality in the steel itself if cold drawn, resulting from the effect of cold drawing and if cold finished under any of the standard methods better machining performance because of freedom from hot rolled scale, close size accuracy, and greater degree of straightness. These advantages are recognized generally by buyers interested in machining quality as indicated by the large percentage of cold finished steels used by machine shops, particularly automatic screw machine work where the machining requirements are most exacting and severe.

Inspection and Testing—To insure a cold finished product that will perform satisfactorily for the diversified application of its users, it is necessary for the steel producer to furnish a quality of the highest caliber. The standards of practices adopted for steel making, preparation and inspection of semifinished sections, and inspection of the final bar are the equivalent of those enforced for forging steels.

Precautions are taken during the making and rolling of the steel to minimize chemical irregularity, seams, pipe, and other defects, surface or internal. After cold finishing, the bars are inspected closely for these same defects, as well as inspected for size, straightness, out-of-round, appearance cutting, and suitable bundling, marking, and loading.

Shafting—It is believed appropriate to include in this discussion a brief mention of shafting formulas; more detailed discussions are published in bulletins of American Standards Association.

Shafts for transmission of power are subjected to transverse and torsional forces. The loads producing these forces are the torque resulting from the resistance offered by the power load to the revolving shaft; the belt pull, the weight of the pulleys, gears, sprockets, drums, and the weight of the shaft itself. In designing a shaft, it is therefore necessary that the stresses to which the shaft is subjected be within the safety limits of the material used.

For ordinary transmission of power through shafting, experience has shown that when velocity of rotation and spacing of shaft hangers are kept within defined

limits, the following formulas answer all practical requirements of design (the limitations of these formulas are that the shafts be supported at no greater intervals than 8 ft. and that the r.p.m. be no greater than 400).

D = diameter of shaft in inches.
N = number of revolutions per minute.
H = horsepower.

For head shafts.....	$H = \frac{D^3 \times N}{125}$
For line shafts.....	$H = \frac{D^3 \times N}{90}$
For short countershafts and single power transmitters.....	$H = \frac{D^3 \times N}{50}$

Conclusion—The uses of cold finished steels have become so widespread that their applications are too numerous to attempt to cover completely. The more common uses are for spark plug shells, radio speaker cores, bolts, nuts and screws, gears and pinions, typewriter, sewing machine and cash register parts, chain pins and rolls for silent chains, motor and transmission power shafting, motorcycle crank axles, oil pump shafts and gears, piston pins, steering gear arms, bushings, pins and worms, tie rods, wringer rolls, gun parts, and commutators. Industries such as manufacturers of automobiles, motorcycles, sewing machines, typewriters, adding and calculating machines, textile machinery, shoe machinery, railroad, agricultural implements and electric equipment are particularly large consumers.

Swaging

By W. L. Bowen, Jr.*

The term "swaging," as used here, refers only to rotary swaging (rotary reduction), and is not to be confused with coining or other types of press work.

Construction and Operation of Swaging Machines—The modern swaging machine is simply a mechanical means for rapidly opening and closing two dies (sometimes four dies). The dies are carried in a slot in the face of a revolving spindle and are held between a pair of steel blocks called backers. Outside of and around the spindle is a circular roll cage containing loosely a number of hardened steel rolls.

The revolution of the spindle causes the backers (and dies) to pass between successive pairs of opposing rolls, thus forcing the dies together. With a spindle r.p.m. of 500 and with 10 rolls, there would be, approximately, 3,000 die blows per min. Actually, this is reduced somewhat because the roll cage rotates slowly, thus lessening the number of blows.

The dies are blocks of hardened steel which have upon their inner faces the impression of the shape or the diameter of the work it is desired to produce, with one end of the die groove flared to allow the unreduced stock to enter, Fig. 1.

Uses of Swaging—Since the dies rotate around the work, it is obvious that the swaged portion must assume a round cross section, even though original work can be of any regular cross section such as square, or hexagonal.

The tapering of tubes (welded or seamless) or drawn steels can best be performed by swaging. Rods, bars and wire are also reduced or tapered economically by swaging. Gold plated wire, for instance, can be swaged with the plate kept intact and evenly distributed all the way to the end of the swaged section.

Speed of Swaging—Naturally the speed of swaging depends upon many factors, such as kind of material, angle of taper, amount of reduction, or finish desired. In general, the speed varies from 1 in. per sec. up to 4 in. or perhaps 5 in. per sec., making little difference whether the work is fed into the dies automatically or by hand, although automatic feeding is always slower than hand unless hydraulic equipment is used.

Physical Effect of Swaging—Swaging is actually performed more by pressure than by blows. Hence there is a flow and readjustment of the grains of the swaged metal.

Most metals tend to work harden when cold swaged so that annealing may often be necessary after one, two, or three swaging passes, depending upon amount of reduction and type of material. This is particularly true of stainless steels.

Some extremely brittle metals, such as a tungsten bar, when hot swaged in a series of passes, can be made ductile enough so that further reductions can be made by drawing.

Since the entire volume of the metal being swaged is not lessened to any appreciable extent, but rather is changed in shape, it follows that solid work, when swaged, tends to elongate. In the case of tubing, swaging tends to thicken the wall, since a volume equal to only 10% of the cross section goes into elongation.

Fig. 1—Three views of the same die showing different values for "L." A shows the total available length, "L," of the die. B and C show two different jobs as swaged with the same die. In B the entire length of the blade section of the groove is used, plus approximately one-half of the taper section of the groove. In C only the length of the taper is being used.

*Sales Manager, Swaging Machine Dept., The Torrington Co., Torrington, Conn. Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steever, chairman; R. W. Thompson, F. B. Foley, O. W. Ellis, H. M. Spears, W. E. Jominy, W. W. Criley, and J. H. Friedman.

The thickening of the wall is simply due to the flowing metal following the line of least resistance.

Amount of Reduction—The amount of reduction in any one pass depends upon various factors such as type of material and angle of taper, but in general the maximum reduction in one swaging pass should not be over 30% of the cross sectional area.

Because the die pressure is in a radial direction around the work, it will be obvious that steep angles or abrupt tapers are to be avoided. For easy, commercial swaging the included angle of taper should not be over 10-12° or less, depending upon force available for feeding.

Swaging Machine Capacities—Various metals have differing ultimate compressive strengths and therefore require varying swaging pressures in order to obtain a reduction. For all practical purposes, flowing or swaging pressures may be considered to be 1.75 times the ultimate compressive stress of the material being cold swaged. (No figures are given for comparative pressures for hot swaging because of the large number of variable factors.)

It must be borne in mind that the figure for swaging pressures given above does not hold good when the length of swage within the swaging dies exceeds ten times the diameter of the work (this applies to solid work only), due to the restriction of endwise flow of the work resulting from surface friction between the dies and the work, which creates pressures in excess of the strength of the dies.

To obtain the maximum capacity of any given swaging machine the following equation may be used:

$$\frac{T}{S \times 1.75 \times L} = D$$

Where D = the dia. of the work, in inches
 L = the length of the die being used, in inches (See Fig. 1)
 S = the ult. compressive stress of the work in psi.
 T = the total capacity of the machine in lb.

The figure for "S" can be obtained from any materials handbook and the value for "T" from the swaging machine manufacturer. Obviously the value for "L" depends upon the job, so may have a different value for each job.

Example—A manufacturer has some material of a certain dia. to be swaged and wants to know if it can be handled without overloading his swager. The swaging machine has a total capacity of 400,000 lb. with a die length of 3 in., all of which length is to be used (Fig. 1).

The material to be swaged has an ultimate compressive stress of 150,000 lb. so the example is solved as follows:

$$\frac{400,000}{150,000 \times 1.75 \times 3} = 0.507 \text{ in. dia.}$$

Thus 0.507 in. dia. work could be safely swaged in this instance.

From the above equation, it is obvious that as "S" is reduced "D" is increased and vice versa, so the allowable projected area in the swaging die grooves (the length of taper \times average dia. of taper) varies inversely as the compressive strength of the material being swaged.

Similarly when only a part of the available length of the swaging die is used, larger dia. work can be safely handled (Fig. 1C).

The limiting factor for "D," of course, is the actual width of the dies. For instance, if it was required to determine the maximum dia. of zinc or a similar material that could be swaged on a certain machine, the value for "S," 70,000, might be so low as to cause the value for "D" (dia. of the work) to be greater than the width of the swaging dies.

Coining

By Guy R. Houghtaling*

Introduction—Coining is a method of cold forming or sizing, by compression, an article made of gold, silver, copper, zinc, tin, nickel or other metals. In recent years, iron and steel parts have been subjected to cold sizing for the purpose of imparting smooth finishes and close tolerances and in numerous instances this coining operation is more economical than producing this finish by cutting tools. A gasoline engine connecting rod is an example where coining is used extensively to size the bosses at crankshaft and wrist pin ends, to within limits of plus or minus 0.001 in. The dies used are generally plain, hardened blocks, having stepped parallel surfaces between which the steel forging (which is about $\frac{1}{2}$ in. larger) is squeezed to size.

Nothing definite can be stated about the percentage of reduction by coining, as each individual job has its limits, which are usually governed by the ability of the steel (in the dies) to withstand constant pressure. A good rule is to use 25% of the ultimate compression strength of the dies in question, for work which is confined. On work which is not confined 50% of the ultimate compression strength of the die steel can be used on production runs.

Methods of Coining—*Drop hammers* can be used when the pressure is not extreme and where the material will flow readily into the dies. Drop hammers exert instantaneous pressure on the article being struck.

Coin presses are usually associated with powerful presses whose slide movement is actuated by a knuckle joint between the slides which is operated by an eccentric or crankshaft.

Screw presses (percussion) utilize a multiple thread screw to which is attached a heavy fly wheel which stores energy and, on a fast downward movement, exerts a powerful pressure on coin dies.

Hydraulic presses are fast becoming adapted to coining work. The modern one unit press can be made to operate fast and with high pressures. These presses can be so regulated that only a definite pressure can be exerted upon the dies. One distinct advantage is that the action of the hydraulic press permits the metal to take a more definite set due to the length of time in compressive action.

Annealed mild steel, with about 0.20% carbon, requires about 50 tons psi. to start plastic flow. This increases as the article becomes harder and the operation must be stopped before reaching the compressive strength of the coining die steel.

Hydraulic presses permit using the greatest amount of the operating time cycle in actual squeezing, having a fast closing of the dies and a fast opening. This sometimes runs to $\frac{3}{4}$ of the time cycle in squeezing, and $\frac{1}{4}$ each to close and open the dies.

Coining Die Steel—The steel for the coining dies is largely a matter of personal preference. Carbon steel, formerly used, is usually shallow hardening and although it becomes very hard on the surface it will not withstand intense pressures. Tool steel manufacturers supply a chromium-nickel-molybdenum drop forge die block steel having about 0.65-0.70% carbon which is pack hardened and oil quenched. This steel has a high compressive strength, holds its shape well during heat treatment and upon proper tempering gives a coining die of long life. Many other steels are suitable, and where simple finishing by machining and grinding can be done, the high carbon high chromium steel is excellent. Modern high production schedules require coining dies to withstand tremendous pressures repeatedly and only steel having the ability to be heat treated for deep hardness fills the above requirements.

Coining Dies are usually made by sinking a hardened hub into a soft die block. This hub is a faithful reproduction of the article to be coined, and from its impression in the die block comes the article to be manufactured. Most of the details in the actual making of coining dies are arrived at by long experience, careful observations, and the most careful and painstaking heat treatments. Metals will work harden when squeezed between coining dies, so to get economical production from the dies, it is important to control this condition by annealing.

Because of the large amount of flow required on numerous articles being coined (for example, men's finger rings), the metal will work harden before it is possible

*Hickok Mfg. Co., Rochester, N. Y. Prepared for the Subcommittee on Forging. The membership of the subcommittee was as follows: Adam Steever, chairman, R. W. Thompson, F. B. Foley, O. W. Ellis, H. M. Spears, W. E. Jominy, W. W. Criley, and J. H. Friedman.

to fill the die completely. It is then necessary to anneal the blank and sometimes to restrike a number of times with an anneal between each strike. As the work hardened metal requires such enormous pressure to make it flow, the coining dies do not have sufficient compression strength to resist sinking, so it is most important to anneal the blanks whenever necessary.

It is very important to have clean blanks at the start of the coining operation and perfectly clean blanks after annealing and before restriking. Most copper base alloys require a red heat to anneal and unless a protective atmosphere is used during heating, the parts will have to be pickled and washed. Coining dies must be kept clean. This can be done with degreasing solvents and frequent use of bristle brushes. Small particles are bound to be removed from blanks during coining and a die can easily be split because of this condition. Another important precaution is to keep the smallest drop of moisture (water or oil) from getting into deep cavities. Metal will not flow into cavities containing moisture.

Various Methods of Coining—Usually, money is coined in a hardened ring, inside of which are the upper and lower dies. Just enough metal is used in the blank to size the coin accurately. Spectacle frames are made from "found blanks" (blanks with just enough metal and proper dimensional sizes to fill the dies). Spectacle parts and jewelry items made of gold filled metal must come from the coining dies with the surface gold unbroken.

Numerous jewelry items are made purposely with a surplus of metal, which surplus is called flash-selva. These dies are economical to make where it is not necessary to hold thickness to exact dimensions. Therefore, any surplus not needed to fill either upper or lower dies is flowed over the edges of both upper and lower dies. This surplus or flash must be carefully controlled. Generally, a good rule is to limit the width of flash to not more than three times its thickness. Where it must be more, flash gutters can be cut in one-half of the die, next to the die line.

Roll Threading and Knurling

By L. A. Ward*

Roll threading is the process of producing a thread by impressing helical grooves in a metal object by means of suitable rollers or dies. Likewise in knurling, a design is impressed in a solid or hollow metal article by means of a roller or rollers which are forced against the work while it is being rotated, the rollers being embossed with the desired design. When considering mass production of bolts, screws, screw caps, and the host of other threaded articles now being produced, the economic advantages of roll threading at once become apparent.

In the case of solid articles such as screws, there is a saving of metal as well as a speeding up of production. A third advantage in the case of bolts and screws is the increased strength obtained by this method due to the cold working of the metal during threading. In the case of hollow articles, the advantages of roll threading are even more apparent, for if it were not for this method of threading the cost of such articles as threaded caps for bottles, flashlights, or electric light bulbs, would be prohibitive due to the necessity for increased wall thicknesses and the added cost of cut threads.

Although there is little published on the history of roll threading and knurling, we do find that as early as 1888 socket shells were roll threaded by the Edison Lamp Works and they had set up standard specifications for this work. Undoubtedly there was considerable of both this type of work and knurling much earlier, but little is recorded.

Knurling—Knurling is commonly done in three different types of equipment, which are: (a) Lathes; (b) automatic screw machines; and (c) special machines. It is felt that a description of the method can best be given by covering these three cases separately.

Lathe—The knurling done in lathes is commonly done on small runs of work, or in combination with spinning operations. It can be done by a hand tool such as is commonly used by a spinner or by a tool which is clamped in the regular tool post and moved against the work in the usual method. The roller for knurling in a lathe, especially when done by hand, is of any convenient diameter (usually about 2 in.). This is made of hardened steel with a design embossed on the circumference and in use this is pressed against the article to be knurled with sufficient pressure to give the desired depth of design.

Automatic Screw Machine—In automatic screw machines the knurling tool can be mounted either on the turret or on one of the cross feed attachments, or as a swing tool. In this article it is not felt necessary to give a detailed description of the tools and cam layouts necessary, as these are adequately covered in instruction books for the various types of machines. The speed used in knurling on brass rod in an automatic screw machine is usually the maximum spindle speed available, although for coarse knurls a slower speed must sometimes be used. The feed for the types of tools shown above is as follows:

Turret:	Feed 0.020 in.
	Return 0.040 in.
Side or swing:	Feed 0.004 in.
	Return 0.008 in.
Top:	Feed 0.005 in.
	Return 0.008 in.

Special Machines—For large volume production, it is frequently more economical to perform the knurling operation in a separate machine. There are a number of machines which are especially designed for this type of operation on either solid or hollow parts.

In these special machines the design of the arbor and pattern rolls is of extreme importance. This is also true for the automatic screw machine and, to a lesser degree, for lathe work. In the case of lathe knurling, the operator can watch the operation and see that the pattern matches as the work revolves, but in an automatic machine this is impossible and if the size of the roller, with relation to the work, is not correct the design will be neither uniform nor properly impressed if the work revolves more than once during the operation.

* Assistant Metallurgist, Chase Brass & Copper Co., Waterbury, Conn.

For hollow parts the arbor and roller are geared together so that they mate properly. The arbor over which the article is placed has the male impression of the design embossed on it, and the size of this arbor is as large as will permit placing the article over the arbor and removing it. The design embossed on the roller is a female impression of the design to be placed on the object. In such machines the work is quite frequently fed into the machine through some automatic feeding device and the entire operation done automatically. Here again there is no need of going into the details of such feeding and knurling mechanisms, and for exact details consulting the manufacturers of these machines is suggested.

Roll Threading—Roll threading may be carried out in three different types of equipment, which are the same as for knurling; namely, (a) in lathes; (b) in automatics; and (c) in special machines. Roll threading is seldom done in ordinary lathes and then only in the case of special threads where it would be either impractical or uneconomical to set up a special machine. Such a case would be where it was desired to put a roll thread on an article which was much longer than would normally be handled.

Lathe—In this case, if it is a rod, a roll is fastened in a suitable fixture on the tool post set at an angle corresponding to the pitch, and the feed is set accordingly. A back rest would normally be used to support the rod, and it is frequently necessary to go over the thread a number of times in order to produce the desired depth.

Automatic Screw Machine—Considerable roll threading is done in automatic screw machines and the tools used are generally similar to knurling tools except that, instead of a design on the roller, a thread is cut on it in the opposite direction to that to be produced on the rod. For instance, if it is desired to produce a right hand thread on the work, the roller will have a left hand thread.

The diameter of the blank to be threaded is approximately the pitch diameter of the final thread. The outside diameter of the threading roll should be larger than the work, and is calculated from the following formula which is taken from the Brown & Sharpe Automatic Screw Machine Operators' Handbook.

$$\text{O.D.} = \text{Pitch Dia. of} \left\{ \begin{array}{l} \text{piece} \\ \text{to be} \\ \text{rolled} \end{array} \right\} \text{ minus } \left\{ \begin{array}{l} \frac{1}{2} \text{ single} \\ \text{depth of} \\ \text{thread} \end{array} \right\} \text{ times } \left\{ \begin{array}{l} \text{multiple} \\ \text{used.} \end{array} \right.$$

It is impossible to give any fixed multiple which will be suitable for all work, but the threading roll should be made as large as possible. Feeds and speed will be approximately the same as for knurling.

Special Machines—There are a number of special machines used for roll threading a great variety of work; for instance, there are special machines for roll threading of bolts and screws as well as those designed for the roll threading of caps and tubular objects. In the special machines for roll threading bolts and screws, the operation is carried out by using two suitable dies having impressions of the thread on their faces. One of these is stationary and the other moves in a plane parallel to the axis of the work and in a direction normal thereto. The dies for this are made of hardened steel and the thread is projected onto these. The blank used is approximately the pitch diameter of the bolt or screw being made. This method of producing a thread on a bolt is one of the most commonly used methods, and its greatest advantage is in the economy of the method and the increased production which is possible. The speed usually varies inversely with the size of the bolt or screw being threaded, but is usually in the range of 30-100 pieces per min.

In roll threading of sheet metal caps and tubular products, the design of thread has never been standardized to the same extent as that for bolts and screws, and there are a number of different systems of threads used. Apparently the only one which is really standard is the one used in the manufacture of electric light bulb socket shells and similar articles. This is the Uno system. Due to this condition, it is quite difficult to give exact information as to the relation of the size of shell to the outside diameter or pitch diameter of the threaded part. Also there is considerably more variation in this respect due to alloy and temper than there is with solid objects. This is due to the wide difference in physical properties from one alloy to another and from one temper to another in any one alloy.

In general, the shell diameter will be slightly larger than the pitch diameter. The arbor size is close to that of the blank so that it is just possible to fit the shell onto the arbor. The roller size is found by subtracting the single depth of thread

from the pitch diameter and multiplying by a factor similar to the method of calculating a roller size for use in the automatic screw machine. We find on special machines for roll threading of shells that multiples as high as 12 are sometimes used, but more commonly the multiple is approximately 4. The arbor and roller are mated through gears as for knurling. The roller, depending on the multiple used, will have a single, double, triple, or quadruple thread. For instance, when the multiple used is 2, there will be a double thread cut on the roller. In use, the shell is usually fed into such a machine automatically and the operation carried out and the threaded shell discharged automatically. Speeds on such machines vary so greatly that it is impossible to give any definite limits.

Although no definite formulae for blank diameters are given for the various types of rolled threads, still the importance of finding and maintaining the correct one is extremely important and frequently the success or failure of roll threading a given article hinges on how accurately this size is maintained. In general too small a blank produces a poorly developed thread which is usually under size, while too large a blank usually produces an over size thread which is frequently rough.

Machinability of Steel*

Part 1—Introduction—In the machining of metals, the metal being cut, the cutting tool, the cutting fluid, the process and type of machine tool, and the cutting conditions all influence the results. By changing any one of these factors, different results will be obtained. It appears impossible to have a set of cutting conditions which will satisfy all phases equally. It is imperative, therefore, to adjust a combination of factors for the most effective compromise.

Definition—Machinability is a term used to indicate the relative ease or satisfaction with which a material is machined by sharp cutting tools in operations such as turning, drilling, milling, broaching, threading, reaming, sawing, or grinding. It is evaluated in several different ways depending upon the objective. These objectives vary widely in commercial machining and may refer to tool performance as represented by the tool life per grind under given conditions; the speed at which the material may be cut under different conditions for a given tool life; the force, energy or power required in cutting; the surface finish produced; or the dimensional accuracy maintained under given conditions between like pieces.

Values of machinability usually are comparative and represent the behavior of the material under given conditions. The tool material, shape, and size; the size and shape of the cut; the cutting fluid used; and the cutting speed must be held constant in order that the values may be directly comparative. If any one of these variables is changed for the tests, other directly comparative results will be obtained which may be out of agreement with those of the first test. Also, the machinability rating of a material as determined by one process may be different from that obtained by another process.

Materials Cut—Many materials have best or optimum cutting conditions, such as speed, feed, depth, tool shape, tool material, or cutting fluid; some or all of which are different from others, so that machinability ratings for these materials for practical purposes should be determined under these optimum conditions. The values of machinability for different materials then will be comparative, although the details of the tests are individual.

Tests for Machinability—The factors of importance in machinability are cutting speed, tool life, power consumption or cutting force, the finish left on the cut surface, and the accuracy of dimensions of the finished product.

Many types of tests have been developed for indicating the machinability of a given metal. If machinability is to apply to the tool, then the material cut should be constant; if machinability is to apply to the material, then the tool should be constant. Cutting fluids may be introduced as the variable, while the material and tool are held constant. Machinability may be expressed as:

1. The life of the cutting tool in turning, milling, drilling, broaching, tapping, or sawing, when cutting under fixed conditions of speed, feed, depth of cut, and with a given cutting fluid.
2. The force, energy, or power required when cutting by various processes, such as milling, turning, drilling, or the energy required to remove a single chip of a given size or shape in milling.
3. The torque and thrust in drilling or counterboring.
4. The suitability as measured by
 - a. The rate of penetration of a drill in a given time under a constant feeding pressure;
 - b. The traverse of a turning tool when fed against the work by a constant pressure as in the case of cutting off; and
 - c. The time in minutes or number of strokes to cut off a given cross sectional area with a hacksaw subjected to a given feeding load rather than a positive rate of feed.
5. The condition of the machined surface produced by the cutting tool on the material being cut.
6. The cost of removal of 1 cu.in. of the metal under specific conditions. This would involve both power and tool cost.
7. The temperature developed at the tool point.

Factors Affecting Machinability—A summary of the factors affecting machinability in accordance with the above definitions are as follows:

1. Material being cut, its analysis, structure, shape, and size.

*Prepared for the Subcommittee on Machinability of Steel by O. W. Boston, University of Michigan.

The membership of the subcommittee was as follows: O. W. Boston, Chairman; A. L. Boegehold, and H. J. French.

2. The cutting speed, size, and shape of cut.
3. The cutting tool, its material, quality, treatment, shape, size, and condition.
4. The condition of the machine tools on which the cutting is done, together with the processes involved.
5. The cutting process. A given material may have different machinability ratings for the different processes as turning, drilling, milling, and grinding.
6. Factors involving rigidity of the tool and work-holding device.
7. The characteristics of the cutting fluid used.

The optimum or best cutting condition involves the material being cut, the tool, the mechanical device, and the cutting fluid. For any material being machined, there is obviously a certain specific combination of conditions which is best. In order to secure the greatest production at the least cost, the cutting tool should be of a given material of a certain definite quality. It should have a certain contour of cutting edge, and combination of angles influencing its geometrical shape. A certain cutting fluid having properties peculiar for the given conditions should be used, and the mechanical equipment for the particular process involved should be suitable. If the physical properties of the material are changed, or if another material is substituted, some of the factors involving the tool, cutting fluid, or mechanical equipment also should be changed to maintain optimum conditions. The present state of the art of metal cutting leaves the selection of the various factors for a given problem to be determined largely by cut and try methods.

The steel cut, the cutting tool, and the cutting fluid used in any cutting operation present variables which affect machinability. Each is discussed separately below.

Part 2—Fundamental Principles—There are several factors involved in the machinability of steel which are closely associated with both the tool and the work, as discussed separately below.

Chip Formation—Chips of ductile metals are removed invariably by plastic flow. They are of two general forms: The ribbon or elementary type, and the sectional type. The elementary type, Fig. 1, is continuous and practically of uniform cross sectional area but made up of very thin transverse slip bands or elements. In the sectional type, Fig. 10, the small elements are grouped into clusters or sections of approximately equal size. Frequently these sections cling together to form a long, continuous chip, the outer surface of which is saw-toothed, but often the various sections become detached, giving broken up chips which are more easily disposed of.

Almost immediately after starting a cut, a small particle of the material being cut is trapped on the face of the tool and forms what is known as a built-up edge. The built-up edge is somewhat triangular in shape, being thickest directly ahead of the cutting edge, becoming thinner as it extends backward over the face of the tool, as shown in Fig. 1. This built-up edge occurs in all types of metal cutting, such as turning, shaping, drilling, sawing or milling. It protects the cutting edge of the tool by causing the undeformed material immediately ahead of the tool point to flow plastically into a chip which slides over the built-up edge on over the face of the tool.

The built-up edge is a function of the analysis and structure of the material being cut, the rake of the tool, the cutting speed, the cutting fluid, and the size of the cut. The thinner the chip, the smaller the built-up edge becomes and the more nearly the cutting edge of the tool cuts the material to leave a smooth finished

Fig. 1—Chip formation with a typical built-up edge on the nose of a lathe tool, turning steel. The bar was stopped suddenly after cutting for some time and the section at right angles to the cutting edge prepared. (Courtesy Hans Ernst).

surface. This surface is smooth, but appears as a torn surface similar to the face of a very fine-cut file. For thick chips, the cutting edge of the tool suffers only a small portion of the total work done, as it is protected by the built-up edge. The built-up edge appears to be a rather permanent structure as long as the cut is continuous. Portions of it may slough off and be carried away on the underside of the chip, and frequently portions of it adhere to the surface of the work as it passes the flank of the tool. See Fig. 1.

At low speeds, the built-up edge for a given condition is largest. As the speed is increased, it is reduced in size, particularly in height. At extremely high speeds, the built-up edge is smallest. When cutting at very high speed, as with cemented carbide tools, the built-up edge disappears and the cutting edge of the tool actually cuts and forms the machined surface which has the highest degree of surface quality.

Chatter—Frequently in the formation of the chips, because of the sliding of the elements into sections or because of the periodic sloughing off of the built-up edge, high-frequency vibrations occur. These vibrations may set up a natural period of vibration of the tool, of the work, or even of the whole machine, which may become very objectionable because of noise, poor surface finish, and possible damage to the machine. Rigidity of tooling, change in speed, feed, or depth of cut, or tool shape may cause the vibration to cease. Whenever long, thin chips are taken, such as with a large nose-radius tool or with a long, straight cutting edge, the danger of vibration is increased.

Surface Finish—The finish on the cut surface is improved as the built-up edge is reduced in size. This reduction may be accomplished by increasing the rake of the tool, using high speeds, reducing the size of the chip, changing the structure of the metal being cut, or introducing a cutting fluid, any one, or a combination of which is commonly used to secure better finish.

Surface finish in itself is a matter of great importance in machining operations of the finishing type.

Surface finish is not only important in connection with surface machining with single-point tools, but with surfaces made by abrasives and other means. The American Standards Association has a Committee on Surface Quality which has been working on this subject for the past six years. The first report was made to industry in Dec. 1938.

Surface qualities, by definition, are the physical characteristics of a boundary which separate solid substances. These qualities include such factors as the geometry of the surface in three dimensions, crystal structure, appearance, color, resistance to corrosion, hardness, size and shape of surface flaws. The committee report deals particularly with the geometry of the surface deviations from the nominal surface (cylinder, flat, sphere). These deviations are of three kinds: Surface flaws, waviness, and roughness, all three of which can be specified in inches. Surface flaws are occasional irregularities; waviness consists of widely spaced irregularities (more than $\frac{1}{16}$ in.), such as feed marks; and roughness consists of finely spaced irregularities (less than $\frac{1}{16}$ in.), which determine what is usually called "finish" of the piece. Flaws and waviness are now measurable, but roughness, being inside the waves, calls for a new measuring technique. The Committee has been concerned with the means of specifying roughness and has adopted the average height of the finely spaced irregularities as a measure of roughness. This height is expressed directly in microinches (millionths of an in.) across the surface in a direction to give the largest reading. It is recognized that this average height of irregularity is by no means a complete specification of any surface and that other information as to the character of the irregularities, as well as waviness, flaws, and other surface qualities, often will be required on practical problems. Consideration is being given to means of specifying some of these other surface qualities. A preferred set of roughness classes has been suggested by the Committee with appropriate symbols which range from $\frac{1}{4}$ microinch to 63,000 microinches, root-mean-square average.

During the past ten years a number of investigators have worked on equipment for measuring surfaces. The most widely used appear to be of three types:

1. Profile recorders which draw an enlarged graph of the actual surface profile. These are laboratory instruments. Two types have been described: (a) The Profilograph which uses mirrors, lenses, and a light beam.^{1, 10} (b) Electric profile recorder using vacuum tubes and cathode ray oscillograph.¹
2. Several arrangements of microscopic observations (profile microscope) with special illumination have been used to enable surface profiles to be observed directly.^{1, 11}

3. A Profilometer is a portable meter which does not draw a record of the profile, but which takes an automatic running average of the height of the surface irregularities and indicates this average directly on a meter. This instrument is portable, self contained, and has found direct application in the shop.¹

Tool Wear—When cutting steel with tools of carbon tool steel, tool failure is usually caused by wear on the flank of the tool directly beneath the active cutting edge. When cutting steel with tools of high speed steel, normal tool failure is caused by a gradual cupping of the tool on its face. After the chip is formed, it slides over the built-up edge protecting the cutting edge, and rubs against the face of the tool some distance back from the cutting edge, as shown at A in Fig. 2. The area of sliding contact between the chip and tool becomes heated, loses its hardness, and is abraded by the flowing chip. A groove is gradually worn into the face of the tool. It becomes larger and larger until its edge meets or nearly meets the cutting edge, as shown at B, Fig. 2. The flank below the cutting edge also may wear, causing the newly formed cutting edge to move toward the enlarging groove, as shown at C, Fig. 2. The built-up edge is gradually reduced in size from the start of the cut until the time the edge of the groove meets the cutting edge. A new irregular cutting edge is formed, resembling a ridge of mountains. The built-up edge at this point apparently disappears. The tool cuts most efficiently under this condition, but unfortunately the irregular mountain-like peaks break off and the tool quickly fails.

The progress of tool wear can be estimated readily from the color, shape, and size of the chip produced. In turning steel, the chips produced are first long and straight or only slightly coiled and are blue or purple in color at proper cutting speed. The color indicates the development of excessive heat even though the tool is newly ground and has cut but a small part of its total life. As the groove in the face of the tool is formed, the chips become coiled either in short spiral or long helical forms of small diameter. In this condition, the chip is at a lower temperature (no longer colored), and the tool cuts for the greater part of its life. As the newly formed cutting edge starts to fail, the chips become irregular in shape, rough on the bottom, and again blue in color.

This manner of wear and failure seems to maintain when taking both heavy and light cuts. The time of complete tool failure is easily observed when taking heavy cuts because of the sudden change in shape of the chips, the high blue color, and the burnished surface of the cut shoulder. When taking light cuts, however, the failure is similar but it is more difficult to determine the instant of tool failure. H. J. French and T. G. Digges⁴ used a trailer tool which was set to cut when the leading tool was worn so the test log became 0.002 in. larger in diameter. It has been found that there is practically no change in diameter of the work because of wear on the tool while taking a light cut until tool failure occurs, so that the trailer tool or any device which will indicate the sudden appreciable increase in work diameter does give a true value of the time of tool failure under light cuts.

Cutting-Speed Tool-Life Relation—For a given steel, tool, and cutting condition the life of a turning tool varies inversely with the cutting speed as indicated by the equation $VT^n = C$, in which V is the surface cutting speed in f.p.m.; T is the tool life under cut up to the time of tool breakdown measured in minutes; n is the exponent of T and equals the tangent of the angle of slope of the cutting-speed tool-life curve when plotted on log-log paper; and C is a constant depending upon the various conditions, such as type of material, size, shape, and material of tool, size

Fig. 2—Tool failure by a gradual cupping.

and shape of cut, and cutting fluid. This relation gives a parabolic curve on cartesian or rectangular coordinates, but a straight line on double logarithmic paper, as shown in Fig. 3.

It is shown in Parts 3, 4, and 5 that the constant C and exponent n will vary for practically every set of conditions as the steel, tool, or cutting fluid is changed, so that no single value of n in the equation $VT^n = C$ can be used safely to represent conditions in general.

Fig. 3—Cutting-speed tool-life curves for various types and conditions of steel plotted on log-log scale. It is shown that each material with different structures gives a different slope to the curve, and that one equation is not suitable for all materials (see text).

determined by a thermocouple at all times during its tool life are shown when cutting dry an annealed S.A.E. 2335 steel at 145 f.p.m. The depth of cut was 0.100 in. and the feed was 0.0125 in. A high speed steel lathe tool was used which had an 8° back rake, 14° side rake, 6° end clearance, 6° side clearance, 6° end cutting, 0° side cutting-edge angle, and $\frac{1}{8}$ in. nose radius. The condition of the tool and the built-up edge at $\frac{1}{4}$, $3\frac{1}{4}$, and 6 min. after beginning the cut are shown in Fig. 2 at A, B, and C, respectively.

Part 3—Steel Cut—The steel cut presents many factors as outlined below, which affect its machinability:

1. Composition, such as carbon, alloy, or special steels developed for free machining which contain sulphur, lead, selenium, of manganese; 2. Melting and casting practice and grain size characteristics; 3. Fabrication: Cast, forged, drawn, or rolled (hot or cold finished); 4. Heat treatment; 5. Physical properties: Tensile strength, hardness, and work hardening capacity; 6. Metallographic structure; and 7. Size of material cut.

Composition, Heat Treatment, and Grain Size (Also see Section on Heat Treatment)—The machinability of steel varies with its composition, treatment, and structure. In cold finished bar stock for screw machine work, the lamellar pearlitic structure is best for the low and medium carbon steels. In the high carbon steel, such as S.A.E. 1095, a spheroidized condition increases tool life. It is reported that the best machinability of normal cold drawn steels is obtained with an elongation of 13-16% in 2 in. and a minimum reduction of area of 40%. There is a danger of reduced tool life if the elongation is below 10% and the reduction of area below 35%. In screw stock steels, well broken up chips, a good finish, and a long tool life at high speed are desirable but not always obtainable together. Alloy steels which work harden appreciably are machined in the hot rolled and annealed condition.

For favorable machinability, a normalizing treatment (or annealing) is recommended by H. W. McQuaid⁶ for the higher alloyed steels. In the case of carbon, carburizing steels, it is seldom necessary to normalize, as satisfactory machinability is usually obtained in the hot worked condition. In the fine grain, shallow hardening type of low alloyed steels, higher normalizing temperatures are necessary to obtain the lamellar pearlitic structure which has the best machining characteristics.

For rough lathe work where surface finish is of minor importance, low hardness is more important than low ductility. For finishing cuts on such steels as S.A.E. 6140, 4140, and 3140, tool life is impaired if the Brinell hardness is over 207, even though the structure is lamellar pearlite.

Steels of fine grain size (A.S.T.M. 5-8), when used as oil hardening or car-

Forces, Energy, Power Relation—Formulas for cutting forces in turning and torque and thrust in drilling are shown in Part 3; tools, Part 4; and cutting fluids, Part 5. It is shown that the values of the constant and exponents may vary as the material or tool shape is changed.

Influence of Tool Wear on Cutting Force—The three components of the cutting force and the temperature indicated in millivolts as

burized steels, are highly ductile, particularly if they are abnormal. They show less warpage in heat treatment and appear to be best for producing a fine finish. W. G. Hildorf states that: "In general, coarse grain size (A.S.T.M. 1-5) is better for heavy cuts. Steel of each grain size should be cut with tools appropriately ground. The resulting cost of metal cutting for each steel with favorably ground tools is approximately the same over a long period of time. Difficulty will be encountered, however, should an attempt be made to machine the coarse grain steels on a machine properly set up for machining fine grain steels."

For further discussion of grain size of steel, refer to the articles by R. L. Wilson.^{4, 12}

Cutting Speeds and Feeds in Turning—When steels are machined in turret lathes with tools of high speed steel properly ground for roughing cuts from $\frac{1}{4}$ - $\frac{1}{2}$ in. in depth and feeds from 0.020-0.060 in., the cutting speeds that give satisfactory commercial values of tool life, as recommended by Warner and Swasey Co., are as follows:

Steel	Surface ft. per min.
Alloy, annealed.....	50- 60
treated	25- 40
Castings, miscellaneous.....	50- 60
Machine, hard.....	35- 60
medium hard.....	60- 85
soft	100-120
Threading	25- 40
Tool, annealed.....	60- 80
unannealed	25- 35

Frequently the tools have to be ground to produce a certain shape of work which calls for reduced cutting speeds. At best the speeds recommended above are for setting up work and may be modified as experience and conditions indicate. The use of cutting fluids may permit cutting speeds higher than those indicated. If Stellite tools are used, these speeds may be increased from 25-75%, depending upon the material being cut and the finish desired. If cemented carbide tools are used, speeds up to 250-300 f.p.m. are possible with the right type of tool. If carbon tool steels are used, the values given should be reduced by 50%.

A large number of types of steels are prepared in the form of bars for use in hand and automatic screw machines. For this work, the cuts are usually much lighter than those used in turret lathes, and for that reason the speeds are generally higher.

The machinability of many of these steels is improved by providing some non-abrasive constituent to break up the continuity of the ferrite. Sulphur is used commonly for this purpose. Steels containing sulphur are known as free cutting steels. For accuracy of dimensions, freedom from rolling mill scale, and improvement in machinability, cold drawing is practiced widely. Usually the hot rolled bars are not equal in machinability to the cold drawn product. Those alloy steels which work harden excessively in cold drawing are often machined in the hot rolled, annealed condition. Good free machining steel has low ductility and it also must possess a low order of work hardness. The tools should be ground so that the chips break up into small particles, rather than form into long coils. Table I lists free cutting steels used as cold finished bar stock, and gives the machinability rating based on the rating of S.A.E. 1112 steel as 100%. These speeds are suggested only for set-up purposes. They may be modified extensively to meet the requirement of the particular operation and cutting fluid used.

Cutting-Speed Tool-Life Relation in Turning—Many examples indicate that the analysis or condition of the steel cut influences the exponent n and the constant C in the cutting-speed tool-life equation $VT^n = C$, described in Part 2. In Parts 4 and 5, it is shown that the tool material and tool shape and cutting fluids also change this equation.

In turning, cast steel containing 25% chromium and 10% nickel, $\frac{3}{4}$ in. square tool bits were used, ground to 8° back rake, 14° side rake, 6° end clearance, 6° side clearance, 6° end cutting-edge angle, 15° side cutting-edge angle, and $\frac{1}{4}$ in. nose radius. In taking a cut 0.050 in. deep and 0.0255 in. feed per revolution, it was found that, when machining the bar as cast, the resulting equation was $VT^{0.088} = 46$, but when machining a corresponding bar after it had been quenched at 2000°F., the equation was $VT^{0.126} = 46$. These two curves are plotted in Fig. 3 and show a considerable

change in the value of the exponent merely through the change in structure. For a tool life of 1 min., the cutting speed for each curve is 46 f.p.m., but for a 60 min. tool life, the cutting speed for the heat treated bar is 25 f.p.m., and that for the "as cast" bar is 35 f.p.m.

Similarly, different bars of S.A.E. 3140 steel $2\frac{1}{4}$ in. in dia. were machined under identical conditions, with a cut 0.0625 in. deep by 0.0377 in. feed, and a high speed steel tool $\frac{1}{2}$ in. square ground to 6° back rake, 12° side rake, 6° front clearance, 6° side clearance, 13° end cutting-edge angle, 0° side cutting-edge angle, and $\frac{1}{4}$ in. nose radius. The bar was heat treated by heating to 1525°F., and after holding for 1 hr., quenching in oil, then tempered at 900°F. for 1 hr. to give a Brinell hardness range of 311-340, an elastic limit of about 150,000 psi., a tensile strength of about 165,000 psi., an elongation in 2 in. of about 16%, and a reduction of area of 55%, the resulting equation was $VT^{0.210} = 100$ as shown in Fig. 3. When a similar bar was annealed by cooling from 1575°F. after 1 hr. at heat, giving a Brinell hardness of 202-207, the resulting equation was $VT^{0.128} = 125$, shown in Fig. 3. The cutting speeds for the annealed bar are higher for all values of tool life than corresponding speeds for the heat treated bar.

Similarly, when machining S.A.E. 1340 steel with the identical tool and cut as outlined in the above, in the annealed condition, an equation was obtained of $VT^{0.200} = 244$. When machined in a spheroidized condition, the equation was $VT^{0.243} = 188$. These lines cross at a tool life of 90 min. The annealed bar permits higher cutting speeds for any tool life less than 90 min., but the spheroidized bar is better for greater values of tool life. Many other similar examples have proved this point.

The cutting speed for a 20-minute tool life, V_{20} , for an S.A.E. 1045 steel when cutting under a given cutting condition with high speed steel tools has a cutting speed of 150 f.p.m. for the annealed bar, about 139 f.p.m. for the cold finished bar, about 102 f.p.m. for the quenched and tempered at 1000°F., about 93 f.p.m. for the quenched and tempered at 600°F., and about 84 f.p.m. for the quenched in oil at 1520°F. This shows a wide variation in cutting speed because of the structure.

When cutting dry an S.A.E. 2340 steel annealed with a high speed steel tool of the 8-22-6-6-6-15- $\frac{1}{4}$ shape, the cutting speeds for 100-minute tool life varied as the size of chip was varied as follows:

A cut 0.0125 in. deep by 0.0125 in. feed gave a cutting speed of 176 f.p.m. and removed 33 cu. in. of metal per tool grind for a tool life of 100 min.

For the same tool life, when the cut was 0.035 in. deep by 0.0125 in. feed, the cutting speed was 120 f.p.m. and the cu. in. of metal removed per grind was 63.

When the depth was 0.100 in. and the feed was 0.0125 in., the speed was 72.5 f.p.m., and the metal removed per grind was 108.8 cu. in.

When the depth was 0.200 in. and the feed was 0.0125 in., the speed was 71 f.p.m., and the metal removed per grind was 213 cu. in.

For the same cross sectional area of cut as the 0.100 in. depth by 0.0125 in. feed, but with the depth reduced one-half and the feed doubled, the cutting speed for a 100-minute tool life was changed from 72.5 to 60 f.p.m., and the metal removed per tool grind was reduced from 108.8 to 90 cu. in.

Cutting-Force Relation in Turning—For a given steel and a turning, planing, or shaping tool, the cutting force in pounds (represented by its tangential T , radial R , and longitudinal L components) varies as the feed F and the depth of cut D , as indicated by the following equations:

$$T \text{ (tangential force)} = C_1 F^x D^y$$

$$R \text{ (radial force)} = C_2 F^x D^y$$

$$L \text{ (longitudinal force)} = C_3 F^x D^y$$

C_1 , C_2 , and C_3 are constants and x and y are exponents. Values of C , x , and y in this equation will vary with the steel or as the tool shape is changed.

The equations for the three components when cutting dry a low carbon steel fully annealed at 80 f.p.m. with a tool ground to 8° back rake, 22° side rake, 6° end clearance, 6° side clearance, 6° end cutting-edge angle, 0° side cutting-edge angle, and $\frac{1}{4}$ in. nose radius, are as follows: $T = 102,500 F^{0.80} D$; $R = 704 F^{0.80} D^{0.12}$; and $L = 12,600 F^{0.48} D^{1.25}$.

These equations, determined by O. E. Kraus, are shown to vary both in the value of the constants and exponents as the shape of the tool is varied, by changing the side and back rake angles, or the nose radius to such an extent that it is difficult to give a general formula.

F. W. Taylor⁴ determined a formula for tangential force on the tool when turning steel from 30-60 f.p.m., as follows: $T = C D F^{0.004}$.

The values of C ranged from 230,000 for soft, medium carbon steel, annealed to a tensile strength of 70,000-296,000 psi. for hard steel. Taylor's $\frac{1}{8}$ in. wide round nose tool was used having a back rake of 8° and a side rake of 14° .

The author has found the equation $T = CD^{.75} F^{.75}$ to hold in turning or planing an annealed S.A.E. 3150 steel. The value of the constant ranged from a minimum of 108,200 when cutting with a sulphurized mineral oil to a maximum of 128,200 when cutting dry. The high speed steel tool had 8° back rake, 14° side rake, 6° clearance, and 6° end cutting-edge angle, and $\frac{1}{2}$ in. nose radius. The setting angle was 90° .

It is evident that the change in material affects very widely the value of the cutting force. Fig. 4 shows the power due to the tangential cutting force when machining a variety of metals as compared to the resistance to cutting by milling and drilling.

Power, Torque, and Thrust in Drilling—Values of torque, thrust, and power were determined from drilling a normalized and annealed chromium-vanadium S.A.E. 6150 steel under various commercial conditions, as shown in Table II. The drills used were standard commercial taper shank drills of high speed steel, the points of which were ground carefully on a machine. For further details regarding drills and for detailed information when drilling other metals, see "Engineering Shop Practice."¹⁰ The feed of each drill corresponded as nearly as could be obtained on the machine to those generally recommended values shown in Table III. The actual r.p.m. is based on a peripheral speed of about 60 f.p.m. for all drill sizes, although torque and thrust are not affected by speed. One part of soluble oil to 16 parts of water was used in all tests.

In order to make it possible to determine the torque T in ft.-lb., the thrust B in lb., or power, for any other combination of drill dia. d in in. and feed f in in. per revolution, the following equations were determined: $T = C f^{.75} d^{1.4}$; $B = K f^{.75} d$. C is the constant for the material, drill, and

Fig. 4—Net values at the tool point of hp. per cu.in. of metal cut per min. for a variety of metals, as determined for drilling, milling, and planing under standardized conditions

Fig. 5—Torque at drill point in drilling S.A.E. 6150 steel.

the following equations were determined: $T = C f^{.75} d^{1.4}$; $B = K f^{.75} d$. C is the constant for the material, drill, and

cutting fluid in the torque formula, and K is a similar constant in the thrust formula. When drilling S.A.E. 6150 steel having a Brinell hardness of 186, the formula becomes: $T_{6150} = 1,840 f^{.75} d^{1.5}$. The thrust formula becomes: $E_{6150} = 53,400 f^{.75} d$. The constants for torque and thrust are shown for a number of other steels in Table IV.

These equations are used to determine the torque and thrust for S.A.E. 6150 steel under any cutting condition. The torque and thrust for any drill diameter and feed may be determined graphically from Fig. 5 and 6, respectively. The torque for a 1 in. dia. drill operating at 0.013 in. feed is shown to be 63 ft.-lb. Similarly, the corresponding thrust is shown to be 1,820 lb.

Table IV also shows factors F_t and F_r for torque and thrust by which the torque and thrust, as determined from Fig. 5 and 6, can be multiplied in order to get the torque or thrust for any one of the other forged steels listed. To illustrate, it is desired to know the torque when drilling S.A.E. 2320 steel with a $\frac{3}{4}$ in. dia. drill operating at 0.012 in feed. From Fig. 5 the torque is shown to be 35 ft.-lb. for the S.A.E. 6150 steel. The torque factor for the S.A.E. 2320 steel is found to be 0.820 in Table IV. The resulting torque for the S.A.E. 2320 steel is equal to 35 times 0.820, or 28.7 ft.-lb.

¹0.35% carbon.

²0.28% carbon.

The total hp. developed at the drill point equals the hp. due to the torque plus the hp. due to the thrust as follows:

$$HP = \frac{2 \pi TN}{33,000} + \frac{B f N}{12 \times 33,000}$$

To illustrate, the 1½ in. dia. drill with a feed of 0.015 in., rotating at 175.1 r.p.m. (60 f.p.m.) when cutting S.A.E. 6150 steel, has a torque of 110.8 ft.-lb. and thrust of 2,430 lb. Substituting these values in the above equation, would give the total hp. as follows:

$$HP = \frac{2 \pi 110.8 \times 175.1}{33,000} + \frac{2,430 \times 0.015 \times 175.1}{12 \times 33,000} = 3.692 + 0.016 = 3.708$$

It is seen that the hp. due to the thrust is only 0.016 or only 0.44% of the total power developed, so for ordinary purposes the hp. output due to the thrust may be neglected. The thrust is of importance in design, however. Table II shows, however, that the efficiency of the machine as determined by dividing the input by the output is highest when using small drills operating at high speed with resulting low values of torque and thrust. Similarly, the efficiency is lowest when the torque and thrust are high, even though the speed of the machine is less. It has been found that torque and thrust are affected but little by a change in cutting speed. The power, however, is a direct function of the speed, as illustrated in the above.

The hp. per cu.in. of metal cut per minute is lower for larger values of feed and drill diameter. In drilling S.A.E. 6150 steel with a ½ in. dia. drill at 0.009 in. feed, a value of 1.443 is obtained. For drilling the same steel with a 1½ in. dia. drill at 0.015 in. feed, the hp. per cu.in. per minute is 1.075.

In another set of experiments¹¹ it has been shown that, when drilling several steels with 11 different types of cutting fluids, the equation for torque as given above holds for all steels. By varying the steels or the cutting fluids, only the constant is changed, as shown in Table V. The formula given for thrust above in connection with the S.A.E. 6150 steel holds roughly, but for more accurate work considering the variation in web thickness w of the drills of different sizes, a more accurate formula for thrust was developed as follows:

$$B = K f^{0.87} \left(\frac{d + w}{5} \right)^{2.13}$$

The performance of one cutting fluid on one steel does not indicate its relative performance on another steel. Actual values of torque and thrust when drilling an annealed S.A.E. 1035 steel with each of 11 cutting fluids are shown in Fig. 7 and 8. (Also see Cutting Fluids, Part 5.)

Table V shows the values of torque and thrust for standard ½ in. and 1½ in. dia. drills operating in each of 4 steels with 3 cutting fluids. The equations for torque and thrust and values of the constants also are indicated.

Fig. 7—The torque required to drill an annealed S.A.E. 1035 steel forging with various drill sizes operating at a speed of 60 f.p.m. and with cutting fluids as indicated: (1) Dry cutting; (2) 1½% borax in water; (3) 1 part soluble oil to 50 parts water; (4) 1 part soluble oil to 10 parts water; (5) No. 1 lard oil; (6) light mineral oil; (7) heavy mineral oil; (8) 10% lard oil; (9) mineral 5% oleic acid; (10) sulphurized mineral oil; and (11) sulphurized base oil blended 1-5 with light mineral oil.

Torque and Thrust Values for Drilling Various Steels Using a 1-16 Emulsion¹⁴

$$\text{Torque in ft.-lb.} = C f^{0.78} d^{1.8}$$

$$\text{Thrust in lb.} = K f^{0.87} d$$

Steel	—Values for the ¼ in. dia. drill— at 0.006 in. feed per revolution		C	K
	Torque in ft.-lb.	Thrust in lb.		
S.A.E. 1020, annealed.....	2.76	306	1,740	104,300
S.A.E. 1035, annealed.....	2.06	281	1,300	96,000
0.97% carbon tool, annealed.....	2.92	390	1,842	133,100
S.A.E. 3150, annealed.....	2.38	318	1,500	108,500
S.A.E. 1112, cold finished.....	1.58	217	1,000	74,100

Similar values for torque and thrust for drills ranging from ¼-½ in. in dia. when operating in the same steels with an emulsion consisting of 1 part soluble oil to 16 parts water are shown in Table VI. The equation for torque shown there for small drills is the same as that for larger drills shown in Table V. The equation for thrust for the small drills shown in Table VI is of a different form, as it does not account for variations in web thickness.

Part 4—Cutting Tools

A cutting tool is efficient according to the length of time per grind that it will cut at a certain speed under given condition (termed tool endurance), to the power consumed by the tool in removing the metal, and to the finish it produces. The smaller the cutting angle (the greater the rake), the more efficient is the cutting action, from a power viewpoint. The sharp lip will not stand up when cutting hard metals so well as the blunt lip. The greater the lip angle, the greater the reinforcement to withstand the cutting force, and to carry away the heat generated. The large rake tool induces the chip to flow over its face with less distortion, while the small rake tool pushes the metal off with excessive shear and compression. In general, a tool may fail: 1. By abrasion on the flank below the active cutting edge; 2. Because of the development by abrasion of a groove on its face behind the cutting edge, which wears forward to the cutting edge resulting in fairly sudden breaking off of the cutting edge; 3. By a combination of 1 and 2; 4. By spalling or crumbling of the cutting edge; and 5. By losing its hardness because of excessive heat generated at the cutting edge.

Types 1, 2, and 3 represent normal types of tool failure. Carbon tool steel tools usually fail by the first method when cutting steel and cast iron. High speed steel tools fail by the first method when cutting cast iron, but normally by method 2 or 3 when cutting steel, as illustrated in Fig. 2.

Factors entering into the performance of tools are as follows:

1. Composition; 2. Melting and casting practice; 3. Fabrication: Forged, ground from rolled bars, cast and sintered solid, tipped and bits; 4. Heat treatment; 5. Physical properties: Hardness, ductility, and hot hardness; 6. Tool form, such as profile of cutting edge, and various tool angles; 7. Tool sharpness; 8. Metallographic structure; 9. Tool setting.

Cutting Tool Materials—Cutting tools must be formed to meet the requirements of the material of which they are made. Cutting speeds and the size of the cut also must be in accordance with the tool material in order to get satisfactory commercial tool life. Cutting tools are commonly made of carbon tool steel, finishing steel, high speed steel, Stellite, cemented carbide, and diamonds. Carbon tool steels are used to some extent where light cuts at comparatively low speeds are permissible, in screw machines on free cutting materials where the tool is well cooled, or where formed tools are stocked for infrequent use. By far the greater majority of tools being used are made of high speed steel. The 18-4-1 type of high speed steel is the most generally used type for all around work. It is uniform in performance. The 18-4-2 type steel generally gives slightly better performance than the 18-4-1 type. The 18-4-3½ type of high speed steel is coming into favor for heavy duty work. Molybdenum steels, such as 8-4-1 and 8-4-2, also are coming into general use where high speed steels are involved. The cobalt high speed steels give up to 25% greater production for certain heavy duty jobs.

Stellite and cemented carbide tools are nonferrous in character. These alloys are cast or sintered to shape, and finally ground. Neither can be forged or heat treated, and both usually are used in the form of tips welded onto the end of heavy steel shanks. Both Stellite and cemented carbide are less ductile than high speed steel and serve best when cutting materials which are abrasive in character. They must be ground with less clearance and rake so as to provide a greater lip angle to support the cutting edge. Both should be supported rigidly so as to avoid bending

Fig. 9—Nomenclature of a ground, straight cutting edge, right-cut, straight-shank, single-point tool. (A.S.A. standard.)

Fig. 10—A section through the active cutting edge A-A of Fig. 9 showing true nomenclature.

or chattering. Terminology applied to a ground tool is illustrated in Figs. 9 and 10, which represent a typical high speed steel, shank-type tool.

Performance of Tools—When cutting a given steel, the analysis or treatment of the high speed steel tool, as well as its geometric shape, have a bearing on its performance. A series of cutting-speed tool-life tests was run with each of four high speed steel tool bits, two of which were of the regular 18-4-1 type of high speed steel, the third was a cobalt high speed steel, and the fourth a molybdenum high speed steel. When ground to a specific shape for turning dry annealed S.A.E. 2345 steel, individual equations were obtained, indicating that the constant, as well as the exponent, of the tool life equation is subject to change because of the tool material.

Influence of the Tool Shape on Tool Life—For a 60 min. tool life, the cutting speed is increased 125% as the radius of the nose of the tool is increased from

0- $\frac{1}{4}$ in.¹⁴ Increasing the side cutting angle similarly shows a great increase in cutting speed for the same tool life. Frequently with side cutting angles greater than 30° on deep cuts where deep thin chips are taken, chatter is likely to occur. This chatter may be eliminated by changing the cutting fluid, the cutting speed, the size or shape of cut, and preferably reducing the side cutting-edge angle. The speed for a 60 min. tool life is increased 55% as the side cutting-edge angle is increased from 0-60°. The side rake angle similarly shows an increase in cutting speed for any given tool life, but when cutting an annealed S.A.E. 2335 steel, the maximum speed was reached for a side rake angle of 22°. However, a 70% increase in cutting speed was obtained by increasing the side rake angle from 0-22°. When cutting soft steel, the greatest tool life for a given speed is obtained when the tool is ground as follows: 8° back rake, 22° side rake, 6° clearance, 6° end-cutting-edge, 45° side cutting-edge angle, and $\frac{1}{4}$ in. nose radius. For harder steel, the side cutting-edge and side rake angles should be reduced.

Influence of Tool Shape on Cutting Force—When taking a cut 0.100 in. deep with a feed of 0.0125 in. in an 0.61% carbon steel of 207 Brinell and 99,000 psi., with a basic tool ground to 8° back rake, 14° side rake, 6° end cutting-edge angle, 15° side cutting-edge angle, and $\frac{1}{4}$ in. nose radius, the cutting force varied as follows: As the nose radius is increased from 0- $\frac{1}{4}$ in., the tangential force remains practically unchanged at 395 lb.; the longitudinal force falls from 185-95 lb.; and the radial force is increased from 25-150 lb. As the side cutting-edge angle is increased from 0-60°, the tangential force remains practically constant at 395 lb. It falls off slightly for the 30 and 45° angles. The longitudinal force is gradually reduced from 173-90 lb., and the radial force is increased from 48-180 lb. As the side rake angle is increased from 0-40°, the tangential force drops from 440-335 lb., the longitudinal force drops from 245-98 lb., but the radial force remains practically constant. A change in back rake angle from 0-16° produces only a slight reduction in tangential and longitudinal forces, but causes the radial force to drop from 75-0 lb.

As the cutting speed is varied for an otherwise given cutting condition, all components of the cutting force remain practically constant at the higher speeds. At the very low speeds, all values of components vary. The temperature between the tool and work, as determined with a thermocouple, rises rapidly until a speed of between 10-20 f.p.m., depending upon certain variables, is reached, after which it increases in direct proportion to an increase in speed.

Cutting Fluids—See the article in this Handbook on Cutting Fluids for Machining.

Abrasive Wheels for Grinding Steel

By A. Rousseau*

Introduction—Grinding has not yet been established as an exact science. Although much progress has been made in that direction during the past few years, it must still be considered an art. It is not possible to determine by mathematics, nor by any other scientific means, the correct wheel for a given operation. Tables and charts based on empirical data and experience are of considerable value in making first selections, but these must be used with judgment, and with an understanding of the general characteristics of grinding wheels and of the effect of certain variable factors which are governed by the work and operating conditions.

Grinding Wheel Characteristics—The characteristics of a grinding wheel are dependent on several variables which are under the control of the wheel manufacturer. The principal variables are the following:

1. Kind of abrasive used.
2. Size of abrasive grains (coarseness).
3. Process by which wheel is bonded.
4. Grade of hardness.

1. There are many kinds of abrasives, known by various trade names, but they can all be roughly classified in the two general groups, aluminum oxide and silicon carbide, each of which is adapted to certain types of work.

2. Approximately 20 more or less standard grain sizes, or degrees of coarseness, are in common use. These grain sizes are usually designated by a numeral which indicates approximately the number of meshes per linear inch of a screen through which the grains will pass. The coarseness of a wheel can be still further varied by using certain combinations of two or more "straight" sizes.

3. Five important processes of bonding the abrasive grains are in common use—vitrified, silicate, rubber, resinoid, and shellac. The characteristics of these processes can be still further controlled by varying the methods of mixing and molding.

4. Vitrified and silicate wheels can be made in about 18 grades of hardness. Most manufacturers designate these grades by letters, using the first letters of the alphabet for the softer grades and the last letters for the harder grades. A few wheel makers run their scale in the opposite direction, while still others use special code arrangements.

Rubber, resinoid, and shellac wheels can be made in about 8 or 10 grades, but here again there is no standard method of designation.

Another method of varying the grinding characteristics of a wheel is by controlling the structure or grain spacing. Wheels can thus be made dense or more open depending upon the requirements of the operation. Surface grinding, for instance, calls for wide grain spacing or "open structure," while cylindrical grinding usually calls for denser structure.

Work and Operating Conditions—The conditions or factors pertaining to the work which are of prime importance in selecting the grinding wheel are the following:

1. Material to be ground.
2. Amount of material to be removed and degree of accuracy.
3. Finish required.
4. Arc of contact.
5. Type of grinding machine.

The effect of these conditions on the grinding operation can be varied greatly by other factors which are, to a certain extent, under the control of the user. The most important of these variable factors are the following:

1. Wheel speed.
2. Work speed (pressure, if off-hand grinding).
3. Condition of machine.
4. Skill of workman.
5. Use of coolant or lubricant.

*Norton Co., Worcester, Mass.

Selection of Grinding Wheel—Charts 1 to 4 show in a general way the factors and rules which affect the selection of the various constituents of a grinding wheel; namely, the abrasive, the grain size (coarseness), the process of bonding, and the grade of hardness. In using these charts it should be borne in mind that they are not laws, but merely empirical rules and as such are sometimes subject to modification to suit individual conditions.

The manufacturers of grinding wheels have classified tables which show the application of these rules to specific problems frequently encountered in the grinding of steel. In these tables are designated the grain, grade, abrasive, and process used.

Causes and Prevention of Checking and Cracking—The checking or cracking of hardened steel pieces after grinding may be traced to either the heat treatment or the grinding operation.

Some of the sources of trouble in the first mentioned cause are too high heats, forcing heats, and carelessness in tempering.

Improper use of grinding wheels and improper methods of grinding also cause difficulty. In some instances it will be found that the wheels used are too hard or that too deep cuts are taken in an attempt to get increased production. Often the work is ground with an inadequate supply of cooling solution, or the solution is not directed to the point of contact. All of these factors lead to the generation of considerable heat which cannot be readily dissipated. This heat is usually sufficient to cause enough unequal expansion between various points on the surface being ground to result in checking.

The methods of eliminating this difficulty depend upon the conditions surrounding any particular job. Some of the more common remedies are:

1. Softer wheels—lighter cuts—quicker passes.
2. Greater flow of cooling solution at the point of contact.
3. Slower wheel speed.
4. Increased work speed.

To prevent checking when surface grinding hardened steel with some types of machines, the following preventative methods are used:

1. Wheels with narrower rim thickness.
2. Additional supply of cooling solution.
3. Finer grained wheels.

This last mentioned factor has solved the trouble in several instances. Several tests have been made where a coarse, relatively soft wheel burned the work and a finer wheel in approximately the same grade did not burn. An explanation of the reason for this may be necessary, as coarser and softer wheels are ordinarily recommended to overcome a burning or hard wheel difficulty.

When surfacing hardened steel with a vertical spindle machine using a cup wheel, the depth of cut permissible is naturally limited. The feed that can be

Chart I
Factors Affecting the Selection of the Abrasive

Physical properties of the material to be ground.....	{	Use aluminum oxide grinding wheels for materials of high tensile strength.	Carbon steels
			Alloy steels
	{	Use silicon carbide grinding wheels for materials of low tensile strength.	High speed steels
			Annealed malleable iron
			Wrought iron
			Tough bronzes
			Tungsten
			Gray iron
			Chilled iron
			Brass and bronze
			Aluminum and copper
			Marble
			Granite
			Pearl
			Rubber
			Leather

taken is governed absolutely by the ability of the abrasive grains to penetrate the surface of the metal. It is difficult to force large grains of abrasive into hardened steel. They can only penetrate a small percentage of the over-all size of the grain, not enough in fact to pull the grains out of the wheel face. As a result they become dull, do not cut, slide over the surface of the steel, and then when a little more feed is applied they start to burn the work. With a fine grained wheel the depth of cut more nearly equals the size of the grains and that allows them to be pulled from the wheel before they become too dull to cut any further. Also in a finer wheel there are more grains to a square inch of cutting surface, hence the material removed per unit of time is greater.

Chart II

Factors Affecting the Selection of the Grit

- | | |
|--|--|
| A. Amount of material to be removed.... | { Use coarse wheels for fast removal of stock.* |
| B. Finish desired..... | { Use fine grain for fine finish. |
| C. Physical properties of material to be ground. | { Use coarse grain for ductile materials and finer grain for hard, dense, and brittle materials. |

Chart III

Factors Affecting the Selection of the Grade (Degree of Hardness)

- | | |
|--|---|
| A. Physical properties of material to be ground. | { Use hard wheels on soft materials and vice versa. |
| B. Arc of contact..... | { The shorter the contact, the harder the wheel should be. |
| C. Wheel speed and work speed | { The higher the ratio of work speed to wheel speed, the harder the grade should be and vice versa. |
| D. Condition of grinding machine... .. | { Machines in poor condition require harder wheels than machines in good condition. |
| E. Skill of operator..... | { Skillful operators can use softer wheels than unskilled—softer wheels mean more economical production.
Piece-work grinding usually requires harder wheels than day work. |

Chart IV

Factors Affecting the Selection of the Process

- | | |
|-----------------------------|--|
| A. Dimensions of wheel..... | { Wheels subjected to bending strains should be made by resinoid, shellac, or rubber process.
Extremely thin abrasive saws must be made by the resinoid, shellac or rubber process.
Wheels over 42 in. in dia. are usually made by the silicate process. |
| B. Rate of cutting..... | { Use vitrified wheels for most rapid cutting at speeds under 6,500 s.f.p.m.; use resinoid, or rubber wheels at higher speeds. |
| C. Finish desired..... | { Use shellac or rubber wheels for highest finish, where rapid production is not a factor.
Use silicate wheels for cutlery. |

*An exception to this rule is made in the case of very hard or tough steels, especially when surface grinding. On such work finer wheels sometimes remove stock more rapidly than coarse ones.

Cemented or Sintered Hard Carbides

By A. MacKenzie*

General—Cemented carbide products are customarily produced by mixing powdered constituents consisting of one or more metallic carbides with a lower melting point cementing or binding material. The mixed powders are pressed in a wide variety of shapes, usually in steel molds under hydraulic pressure. To facilitate handling and forming, the pressed pieces may be "presintered," in which condition they can be shaped with steel tools. After such shaping, final hardness is obtained by heating to a higher temperature. Both sintering operations are made in a furnace having a nonoxidizing atmosphere.

Powdered Constituents—The powdered constituents in general use are monocarbides of tungsten, tantalum, and titanium, or combinations of these. Cobalt and nickel are the most common lower melting point cementing agents. In some combinations, minor percentages of other metallic substances are added or are present as contaminations.

Cemented tungsten carbide, with cobalt as the binder, is—and has been—the predominating combination. The cobalt content varies in accordance with the desired combination of properties. Combinations of tantalum carbide, tungsten carbide, with or without tungsten metal powder, and with nickel as the binder, also have desirable properties in the opinion of Philip M. McKenna.

Technique—Carbide—The carbides are ordinarily formed by adding carbon in the form of lampblack to the powdered metal or oxides, then heating in a suitable atmosphere to temperatures usually ranging from 1500-2400°C. The proper combination of time and temperature for carbon absorption is different for each element.

The carbide, before mixing with the cementing material is in a finely divided state with varied size of particles, a maximum particle size of 15 microns being usual.

The Cementing Material and Its Introduction to the Carbides—The prime cementing material, cobalt, is produced in powder form, generally by reduction at low temperatures from the oxide.

Intimate mixing of the metallic powder, so produced with one or more of the carbide powders, is attained by ball milling. One purpose of milling is to coat all carbide particles with a film of cementing material. The time of ball milling varies for each type of product, but as a rule it increases as the binder content decreases.

In some processes, it is reported that the ball mill lining is of the same material as the final binder in the cemented carbide, and that the binder is obtained from this lining. In such processes, the time of milling is so established that the proper amount of binder is incorporated during the milling period.

Pressing—At this stage in the process, the powders are given definite form. The usual pressing operation is one in which the powder is placed in a hardened and ground steel mold, then compressed under hydraulic pressure. Varying pressures are used, but the common practice is from 15-30 tons per sq. in.

The practice is to press a slab or ingot approximately 1-1½ in. wide by 7-11 in. long, and in various thicknesses.

In special cases, particularly wire drawing dies, molds are made to press specific sizes and shapes.

In all cases, with this process, the molds and powder are handled at room temperatures. In the art, the process is known as the *cold press method*.

Another process, not now widely used for production purposes, is known as the *hot press method*. This involves pressing and sintering the powder simultaneously. This process uses carbon molds inserted between electrodes and heated by resistance. The pressure is applied simultaneously through carbon plungers during the heating cycle. These carbon molds can be machined to predetermined shapes, but, in the majority of cases, can only be used for pressing one piece. This method is not as amenable to control as the cold press method, and is more costly.

Presintering or Semisintering—These terms are in use to indicate the heating

*Carbology Dept., Cleveland Wire Works, General Electric Co., Cleveland.

step in the process which slightly hardens the pressed pieces so they can be handled and shaped.

The pressed pieces, as removed from the molds, are placed on graphite slabs and put into electric muffle furnaces with suitable atmospheres and at temperatures of about 850°C.

Forming—On removal from the presintering furnaces, the pressed pieces can be turned in lathes, or cut to definite shapes or forms, with ordinary tools. At this stage, the material might be classed as chalk-like, although much more abrasive.

The density of semisintered cemented tungsten carbide material is about 9, while the sintered material will run up to or above 15.

A substantial shrinkage in volume takes place during the final sintering operation, so in forming or shaping this shrinkage must be allowed for.

Sintering—This is accomplished by heating through a definite cycle under controlled atmospheric conditions. The product, in this step, attains its final physical state.

For sintering in an electric furnace, the formed pieces may be placed in carbon boats and passed through the furnace under definite time and temperature control. The time and temperature will vary, depending on the composition of the material being sintered, and the size of the mass.

For the furnace atmosphere, hydrogen is in general use, although other gases having nonoxidizing characteristics are, and can be, used. Vacuum is sometimes resorted to, especially with combinations rich in tantalum carbide.

The phenomena causing change in dimension and physical characteristics during the sintering operation are complex; and not completely understood.

Wyman and Kelley¹, reporting on their study of the action of the cementing material in cemented tungsten carbide, concluded "that the binding constituent in the cemented tungsten carbide materials usually reaches the liquid state during the final sintering operation, at which time it consists of tungsten carbide dissolved in cobalt. It is believed that upon solidifying this cobalt-rich cementing material remains as a solid solution of tungsten carbide in cobalt."

S. L. Hoyt² in a description of the forces set up during sintering, suggests that "the formation of a liquid phase, which wets the surface of the carbide particles, sets up tensile forces of surface tension that tend to pull these particles together." There are known instances of approximately a 2 in. total linear shrinkage starting from a 16 in. length.

Minute porosity is encountered in most cemented carbides. Some reasons are: Entrapped gas; impurities; improper rate of heating; improper particle distribution; or improper pressing technique. Much progress in eliminating these defects has been made by the various manufacturers through better raw material and process control.

Properties of Cemented Carbides—The physical properties vary with the different combinations of constituents. In addition, physical properties for the same combinations, can be, and are, changed by processing.

The values listed in Table I are representative of specific compositions and processes only. They do not necessarily represent the ultimate properties in identical combinations. The various values given for each combination are not necessarily taken from the same specimen.

According to S. L. Hoyt, the modulus of elasticity on a 13% cobalt sample has been determined by A. L. Kimball, of the General Electric Research Laboratory, to be 79,000,000 psi., with an accuracy of about 0.5%. This is higher than any other known material, and is well above tungsten, which has a modulus of 60,000,000 psi., and which, in turn, has twice the modulus of steel. On compositions of high tantalum carbide content the Research Laboratory of the Vanadium Alloys Steel Co., reports a modulus of elasticity of 56,000,000.

S. L. Hoyt states that J. V. Emmons, of the Cleveland Twist Drill Co., determined the torsional modulus of elasticity on a 13% cobalt sample as being 17,250,000 psi., and of highspeed steel as being 8,150,000. The highspeed steel was hardened at 2350°F., after 30 seconds and drawn at 1040°F. for 30 minutes. The size tested in each case was 4% in. long by 0.310 in. diameter.

^b30 kg. load.

^dDr. P. W. Bridgman, Harvard University.

The thermal conductivity of a 13% cobalt sample has been determined by H. A. Robinson at the Massachusetts Institute of Technology, and found to be 0.652 watts per cm. per sec. per °C. with a deviation of ± 0.025 . This conductivity is about 50% greater than that of tool steel. The thermal conductivity of a tantalum carbide composition (78% TaC) is about 0.224 watts per cm. per sec. per °C. as determined by William Newcomer of the Vanadium Alloys Steel Company Research Laboratory.

Cemented Tantalum and Titanium Carbides—Commercial cemented tantalum grades range from tantalum carbide with a binder to grades having varying percentages of tantalum carbide and tungsten carbide plus the binder.

For certain applications, the commercial grades of cemented tantalum carbides have advantages over cemented tungsten carbide grades in resistance to certain types of corrosion.

In addition, cemented tantalum carbide has a lower coefficient of friction against steel than cemented tungsten carbide. This is a beneficial characteristic in the application of the material to steel cutting, as the heat generation is lessened and the resistance to loading, or cratering on the cutting edge, is appreciably increased.

Cemented carbides containing titanium carbide are predominately, in so far as weight is concerned, tungsten carbide with the titanium carbide as a minor, though potent, constituent. Grades containing titanium carbide have been developed and are being used for steel cutting applications.

Properties of Tantalum and Titanium Carbide—Physical properties of representative combinations of the cemented tantalum carbide grades and the cemented titanium grades are listed in Table II.

Product Control Methods—Hardness, density, strength, and microscopic examination are used for production control and experimental evaluation. In addition, field tests, under actual operating conditions, are extensively used for determining the merits of new combinations.

Hardness Determination—The most commonly used method is the Rockwell test. The manufacturers of cemented carbides have established an arbitrary standard using the standard diamond penetrator and reading on the C scale, but with the 150 kg. major load removed, using instead the 60 kg. major load. This new standard has become known as the "A" scale. No mathematically exact conversion figures from the Rockwell A to the Rockwell C scale exist.

To assure proper hardness readings on cemented carbides requires careful preparation of the sample. All surfaces on which readings are to be taken should be ground, and preferably lapped, parallel to the ground, and lapped bottom surface. It is difficult to obtain proper readings on cemented carbide parts while brazed to, or held, in steel supports. Hardness values for a given carbide content usually increase as the binder content decreases.

Table II
Properties of Tantalum and Titanium Carbides

Combination	Hardness, Rockwell A Scale	Density g./cc.	Modulus of Rupture, psi.
Predominately tantalum carbide plus 13% binder.....	87.0	13.55	175,000
Equal amount of tantalum carbide and tungsten carbide plus 13% binder	87.2	13.65	250,000
Predominately tungsten carbide plus tantalum carbide and 13% binder	87.5	13.91	275,000
80% tantalum carbide, 12% tungsten metal, 8% nickel.....	88.4	250,000
75% tantalum (Columbium) carbide, 13% tungsten metal, 13% nickel	88.3	275,000
72% tantalum (Columbium titanium) carbide, 20% tungsten metal, 8% nickel	91.0	185,000
Predominately tungsten carbide plus titanium carbide and 13% binder	89.8	12.80	250,000
Predominately tungsten carbide with increased amount of titanium carbide and 13% binder.....	90.0	11.95	240,000
Predominately tungsten carbide with increased amount of titanium carbide and 13% binder.....	90.0	10.10	180,000

Hardness values should not be used as indicators of cutting tool or die efficiencies, especially where a comparison of one carbide combination with another is being made. Under properly controlled manufacturing conditions, little or no variation in hardness for a given grade should be encountered, so this method is valuable for control purposes.

Density Determinations—This test is the usual water displacement one of weighing the piece dry and then in water, using an analytical balance, and calculating the density from the difference in weight. This acts as a check on constituents and porosity against previous standards or theoretical densities.

In the cemented tungsten and tantalum carbide combinations, the density increases as the binder decreases. With combinations having sufficiently high titanium carbide, the density will decrease as the binder decreases.

Strength—The hard cemented carbides possess little or no ductility. The strength is measured by calculating the modulus of rupture or maximum stress in the outermost fibre by means of test bars ruptured transversely. Values as high as 400,000 psi. for 13% binder, and 280,000 psi. for 6% binder, have been attained. Comparable readings on high speed steel have been 400,000 psi., and on superhigh speed steel up to 600,000 psi.

Microscopic Examination—Samples of cemented carbides are examined and photographed at magnifications up to 1500.

Samples of cemented carbides may be prepared for microscopic examination by first grinding with a silicon carbide or a diamond impregnated wheel, then lapping with No. 5 diamond dust or a fine diamond impregnated wheel, and then polishing with a fine diamond dust.

An etching solution containing equal parts of a 10% solution of KOH (Potassium Hydroxide) and a 10% solution of $K_3Fe(CN)_6$ (Potassium Ferricyanide) is one of the solutions in use. The length of time for etching is from 3-5 min.

Application of Cemented Carbides—The use of cemented carbides can be divided into three classes: (a) As a die material; (b) as a cutting tool material; and (c) as a wear and corrosion resistant material.

(a) **Die Applications**—These materials are generally used for the drawing of bars, rods, wire, and tubing, and in a wide variety of sizes and shapes. Extrusion, sizing, deep drawing, forming, eyelet, and burnishing dies, as well as mandrels, are also widely used.

There are few restrictions for this die material, except size, as it is used with many materials and for many operations. Some examples may be listed as follows:

For the cold and hot drawing and extrusion of wire, bars, and tubing from

high and low carbon steels, alloy steels, stainless steels, tungsten, molybdenum, nickel, and nickel alloys, aluminum alloys, copper, brass, zinc, and precious metals. For the extrusion and sizing of bolt and screw stock. For the drawing and forming of eyelets, lamp bases, metal radio tubes, shells, and ferrules. For nut burnishing.

(b) *Cutting Tools*—Cemented carbides are used for machining all types of metallic parts made from cast iron, aluminum, brass, bronzes, copper, babbitt, zinc, and all their alloys. In addition, they are extensively used in machining nonmetallic materials and resinous products such as hard rubber, celluloid, Bakelite, asbestos fibre, casein, vegetable ivory, porcelain, linoleum, catalon, Masonite, wood, and carbon.

Steel cutting with cemented carbides presents more hazards because chip or cut pressures are generally much higher than with cast iron. A phenomenon associated with these increased cut pressures, and which leads to early failure, is *cratering* or *loading*. This is the result of fragments from the chip welding to the tool material and causing minute particles to break out. In time, as the crater increases, the cutting edge breaks away and the tool fails.

Tantalum carbide and titanium carbide compositions resist this cratering much better than cemented carbide compositions containing only tungsten carbide and a binder.

Progress has been made in steel cutting with these cemented carbides. Certain types of application, such as precision boring of automotive and other type connecting rods, as well as the many applications involving light finishing cuts on the harder types of steel are successfully carried out. The number of applications on steel cutting are definitely increasing.

Types of Tools Used—A partial list of the many types of tools that are being tipped with cemented carbide is given below. The size of single purpose tools in the various classifications will vary from $\frac{1}{4}$ in. square or round up to 3 and 4 in. square.

Single point turning, boring, facing, chamfering, and planer tools

Grooving tools for straight and form grooving.

Form tools—flat and circular.

Blades for inserted type milling cutters, adjustable reamers, and saws

Drills, both flat and spiral.

In addition, multiple tipped solid shank tools are in use such as—

End mills	Core drills
Side mills	Spotfacers
Hollow mills	Counterbores
Profiling cutters	Valve seating tools
Multiple tipped form and grooving tools	Broaches
Step drills	Saws
Reamers of many types	

Although each job has its peculiar characteristics and no one value can be given which covers a whole class of work, a recent report of the Subcommittee on Metal Cutting Materials of the A.S.M.E.³ indicates average production increases through the use of cemented carbides as being:

Cast iron—10-200%, the average being about 60%.

Steel—Increases of from 10-80%, with the average about 35%.

Aluminum, brass, bronze, special alloys, and other nonferrous materials indicated, increase from a minimum of 15% to a maximum of 500%.

The same report indicated saving in cost of production as follows:

Cast iron—from 5-75%, averaging about 28%.

Steel—from 5-50%, averaging about 22%.

Other materials—from 20-75%, averaging between 20 and 40%.

The same report also has the following to say about cutting speeds:

"Cutting speeds, feeds, and depths of cut being used successfully, varied greatly. About all that it is possible to do here is to give an idea as to the average speeds being employed on various materials.

"On cast iron roughing cuts, the cutting speeds ran all the way from 55 ft.

per min. up to 500 ft. per min., the average being about 175. On finishing cuts, the speeds were from 70-580 ft. per min., the average being 245 ft. per min.

"On brass and bronze, the cutting speeds ranged from 150-2,250 ft. per min., average about 510. On soft steels, the speeds ranged from 95-400 ft. per min., average about 200. On hard steels, the speed range was 40-300, average 135. The tendency was toward high speeds and light feeds in general."

Suggestions for Handling Cemented Carbide Tools—A few general suggestions on handling of cemented carbide tools together with general recommended cutting angles follow:

(1) *General Handling*—When handling cemented carbide tools, care should be taken not to abuse the carbide tip. Do not drop the tool or tap the tip with a hammer while setting up. Carbide tools can stand a certain amount of abuse, but consideration should be given at all times to the fact that cemented carbides are hard, and, usually, easier to break than steels.

(2) *Setting Up*—In setting up a job, the customary procedure may be followed in general. There are, however, certain factors which must be observed to get the greatest performance from cemented carbide tools. Briefly, these are as follows:

- (a) Keep the tool overhang at the absolute minimum which will allow the tool block to clear the work.
- (b) Use the proper size tool for the job. Do not use small bits and tool holders for large work.
- (c) Use only the tool holders specially developed for cemented carbide tools. These are designed to keep the base of the tool on a horizontal plane.
- (d) Set tools to cut on the center line of the work.

(3) *Depth of Cut*—

- (a) In all cases, the depth of cut should never exceed the length of the cemented carbide tip. In other words, all contact with the work should be against the cemented carbide tip and not permitted to extend into the steel shank.
- (b) In general, on jobs where a large amount of stock is to be removed, the capacity of the machine, rather than limitations of the cemented carbide tool, usually govern the depth of the cut.
- (c) When machining castings with tough scale, cemented carbide tools can take a light cut just under the scale and stand up for economical periods. Because of this, castings can be made closer to finished size than when using steel tools.
- (d) Where the thickness of metal to be removed is not great, frequently the rough and finish cuts, or rough and semifinish cuts may be combined when using cemented carbide tools.
- (e) When starting cut on irregular pieces, use care to avoid excessive depth of cut.

(4) *Feed*—When starting cemented carbide tools on a new job, it is usually desirable to start with a $\frac{1}{2}$ reduction of feed ($\frac{1}{2}$ less than previous practice with high speed steel tools) and increase until the most economical feed is reached. Speeds, of course, must be considered when adjusting feeds. (See *Speed* below.) In general, the following should be observed: (a) Always disengage feed before stopping work (or if work is stalling). (b) In starting on irregular pieces, use care to avoid excessive feed.

(5) *Speed*—In general, it is suggested that you start cemented carbide tools at approximately double the speed used for high speed steel tools on the same application. From this point on, the most economical speed will depend upon the condition of the machine tool, output requirements, the relation of the operation to subsequent and preceding operations, the grinding and the set up time, and the number of pieces obtainable between grinds. It is obviously impossible to set down any definite figures of exact speeds recommended, due to variable factors on every job and variations in the material itself to be machined. But with the knowledge that speed can be increased greatly with cemented carbide tools, and in most cases at least 100%, satisfactory practice on the particular requirements can be quickly established.

(6) *When to Use Coolants*—Use of cemented carbide tools does not alter the rule for use of coolants. Use the same practice previously employed. One factor should be observed, however. When using coolants, it is absolutely essential that a heavy, continuous flow be provided to prevent alternate heating and cooling of the tool.

(7) *Chucks, Clamps, and Holding Devices*—Chucks, clamps, and holding devices should hold the work solidly to prevent loosening during the machining operation.

This is particularly necessary at the higher speeds used with cemented carbide tools.

(8) *Grinding*—To obtain the greatest value from cemented carbide tool investment, tools should be reground before they become dull to the actual point of failure. By so doing, it is usually only necessary to remove a few thousandths from the tip to renew the cutting edge. Occasional stoning will also be found helpful in increasing the life of the tool. Special silicon carbide stones are available for this purpose. In addition, special diamond impregnated stones, or hones, as well as silicon carbide and diamond impregnated grinding wheels, are available. Diamond impregnated wheels are proving satisfactory for the resharpener and maintenance of cemented carbide tools. Proper maintenance of tools by users is essential to the successful use of cemented carbides.

(9) *Interrupted, or "Jump", Cuts*—Cemented carbide tools are being used with satisfactory results on interrupted cuts. However, lower speeds should be used than on continuous cutting. On severe jobs, the design of the tool should provide greater support for the tip than is ordinarily required.

Design Recommendations—Proper support is the most important requirement to be considered in the design of cemented carbide tools. Being hard, and usually not so strong as steel tools, the cemented carbide tip must have adequate support to perform efficiently. Based on this general requirement, the following conditions for rake angles and clearances should be provided:

- (a) Avoid all sharp angles which throw the stress upon an unsupported section of the cemented carbide tip rather than into the shank.
- (b) For clearance angles, provide only the absolute minimum necessary to clear the work.
- (c) For rake angles, the correct design is that which keeps all angles at a minimum consistent with the cutting qualities desired. Design of previous tools may be used as a guide in determining where angles are necessary, but the degree of angles should be kept to an absolute minimum. In general, it will be found that the angles used on previous tools may be substantially reduced without jeopardizing the cutting qualities of the cemented carbide tool.

The following recommendations may be used as a general guide in determining correct angles. Those recommended may, of course, vary according to the individual requirements of any given job, but the figures shown will give some indication of correct cemented carbide tool practice:

	Clearance	Side Rake	Back Rake
Aluminum	8°-12°	12°-16°	20°-40°
All other nonferrous.....	6°-12°	5°-15°	0°- 6°
Ferrous metals (except steel).....	4°- 6°	3°-10°	0°- 4°
Nonmetallics.....	8°-10°	5°-15°	3°- 6°
Steel	6°- 8°	10°-20°	4°-10°

(c) *Wear and Corrosion Resistant Applications*—The cemented carbides are being used where localized wear or corrosion is a problem. This classification includes small tools, as well as parts and accessories for production machines. Typical applications are as follows:

Lathe and grinder centers (male and female).
 Lathe work and follow rests.
 Centerless grinder work rest blades.
 Grinder fingers, profiles, and cams.
 Gages of all types, micrometers, indicator points.
 Colling guides, colling arbors.
 Guides, all kinds, for the wire, paper, textile, and shoe industry.
 Valve stems and seats for hydraulic presses and refrigerators.
 Ball valve and seats for oil well and other type pumps.

Meter fingers and pawls.
 Sandblast nozzles.
 Burnishing tools and dies.
 Chilling plates for the hardening and tempering of thin stock.
 Straightening and flattening dies or blocks.
 Mold liners for pharmaceutical, ceramic, and powdered metal arts.
 Grinder parts for the fine grinding of paint pigments, carbon products, and other abrasive materials.
 Brinell balls.

The cemented carbides are limited to the smaller applications of the above general type and should not be considered for such items as tank linings, gear teeth, or tractor treads.

An interesting application is the use of a cemented tungsten carbide grade as a contact material on relays and transmitters in telegraphic systems.

The fact that certain cemented carbides have compressive strengths higher than other known materials has been instrumental in furthering a new field of experimentation by which pressures of 50,000 kg./cm.² are being applied to solids, and the parameters of any transitions measured. This work is being conducted currently by P. W. Bridgman² at the Research Laboratory of Physics, Harvard University. The cemented carbide material is being used as the pistons for applying the high pressures used.

Fabrication of Dies, Tools and Wear Resistant Parts—The cemented carbides are applied to the above type applications as solid pieces, or generally as inserts brazed or mechanically attached to steel or other supporting members. The attaching and processing of the cemented carbides after final sintering is described below.

Dies and Mandrels—The nibs or inserts, as removed from the sintering furnace, are generally ground on all outside faces to given dimensions and to close tolerances. The small ground die nibs are press fitted into alloy steel, stainless steel, Monel or bronze cases.

The large ground die nibs are put in alloy steel casings while the casing is at an elevated temperature. On cooling, the steel case shrinks around the die nib and holds it securely.

This procedure is also used for holding cemented carbide die nibs which have been made in more than one piece. Shaped dies and exceptionally large round dies are generally fabricated in more than one piece.

Other methods in use for the holding of die nibs are: Casting of a case around the nib; forging of a case around the nib; and in some instances a brazing procedure is followed.

Cemented carbide tipped mandrels generally have the tip in the form of a cylinder. This cylinder is held mechanically by means of a closely fitted screw threaded into a heat treated shank.

After the cemented carbide nibs or inserts are mounted in the supporting case, they are finished to the form, size, and polish desired by the use of powdered abrasives. The powdered abrasives in general use are diamond, boron carbide, and silicon carbide, and their ability to remove stock is the order listed with the diamond occupying the pre-eminent position.

The diamond powder is obtained by crushing, or breaking up, small industrial diamonds known as bortz. This crushed product is graded into several grades of powder by floating the diamond particles in olive oil under definite controlled time schedules. Boron carbide and silicon carbide powders are generally graded by sieving.

Special drilling and polishing equipment, using above abrasives, as well as technique, has been developed and is in general use for the manufacture and recutting of cemented carbide dies.

Tools, Wear and Corrosion Resistant Parts—The same general technique is followed for tools and wear resistant parts, so both are included under the one heading.

Cemented carbide tools and wear resistant parts are generally made up with the cemented carbide as a tip or insert. The remainder of the tool is generally a steel shank or holder.

In some instances, the cemented carbide is used as a tool or part without a supporting integral unit. These parts, however, are generally clamped, or inserted, into steel holders of one kind or another.

Brazing is the method widely used for attaching the cemented carbide tip, or insert, to the steel shank or holder. The brazing media in general use are copper, tobins bronze, and silver solders with suitable fluxes for each.

Most production brazing is done in either an electric or gas furnace which is generally of the muffle type. Whether gas or electric, the furnace should have a nonoxidizing atmosphere.

Many users satisfactorily braze their own tools using oxy-acetylene or oxy-hydrogen torches.

The shanks are generally made from steels having a carbon content of from 0.40-0.60% and of the low alloy type. A wide variety of steels can be used with

average success, but to date it has been found that a silicon manganese steel of the *chisel steel* type has the best all around properties.

The final grinding is usually done on standard tool room equipment, using silicon carbide or diamond impregnated grinding wheels. When necessary, the tool edges can be lapped, either with a cast iron disc and diamond powder, or with a diamond impregnated lapping wheel.

Cutting Fluids for Machining*

Part I

Definition—Cutting fluids, frequently referred to as lubricants or coolants, consist of those liquids, solids, and gases which are applied to the material being cut and the tool to facilitate the cutting operation. Suggested lubricants for cutting and forming dies operations are discussed in Part II of this article.

In metal cutting, it is desirable to have high cutting speed, long tool life, low cutting temperature, low power consumption, the best surface finish, and freedom from corrosion. In different operations these factors vary in importance and usually some are obtained at the expense of others. For instance, in heavy roughing cuts, temperatures as affecting distortion and surface finish are of little consequence. In screw machine work, however, surface finish, dimensional accuracy as affecting interchangeability, and long tool life are of great importance. For each case, desired results are obtained by varying the tool material and shape; the cutting speed, feed, and depth of cut; the structure of the material cut; and the cutting fluid.

Purpose of Cutting Fluids—A cutting fluid is used for the following purposes: 1. To keep the tool cool and prevent it from being heated to a temperature at which the hardness and resistance to abrasion are reduced. 2. To keep the work cool, thus preventing it from being machined in a warped shape resulting in inaccurate final dimensions. 3. Possibly through lubrication to reduce the power consumption, wear on the tool, and the generation of heat. 4. To provide a good finish on the work. 5. To aid in providing a satisfactory chip formation. 6. To wash away the chips (this is particularly desirable in deep hole drilling, hacksawing, milling, and grinding). 7. To prevent corrosion of the work and machine. 8. To lubricate moving machine parts close to the cutting tool.

Classification of Cutting Fluids or Coolants—Cutting fluids and coolants may be divided into the following classes: 1. Air used as suction or blast. 2. Water, either plain or containing an alkali. 3. Emulsions of a soluble oil or paste. 4. Oils, such as mineral, fixed, compounded, and sulphurized.

Types of Cutting Fluids and Their Applications—Air as a suction is often used with internal and surface grinding and polishing operations or on grinding and boring operations on gray iron. Its main purpose is to remove the small chips or dust from the air, although some cooling is obtained.

Aqueous solutions, containing up to 1 or 2% by weight of an alkali, such as borax, sodium carbonate, or trisodium phosphate, have high cooling properties and have sufficient corrosion prevention properties for some jobs. They are inexpensive and are sometimes used for grinding, drilling, sawing, light milling, or turning operations.

Emulsions consist of an emulsifying soluble oil or paste emulsified with water in the ratio of 1 part oil to 10-100 parts of water, depending upon the type of product and the operation. This is low cost cutting fluid and is used for practically all types of cutting and grinding when machining all types of metals. The richer mixtures of oil and water, such as 1-10, are used for broaching, threading, and gear cutting, where an oil is not required to secure the desired surface finish or machine lubrication. For most operations a solution of 1 part soluble oil to 20 parts water will be satisfactory for turret lathe work, some screw machine work, gear hobbing, and drilling. Leaner mixtures may be used on simple turning or drilling operations. Lean mixtures, such as 1-50 or up to 100, may be used on some drilling and most grinding operations. In many instances the concentration of the emulsion is determined by the rust prevention requirements of the metal being machined or the lubrication requirements of the machine and not by the actual machining operation.

A variety of oils are used for metal cutting. They are used where lubrication rather than cooling is essential, or where a high grade finish is desirable, although sometimes superior finishes are obtained with the emulsions.

Sulphurized oils are used generally as cutting fluids for rapid production involving good surface finish and close tolerances on metals difficult to machine. These sulphurized oils may be classified into three groups as follows:

1. Sulphurized mineral oils—These cutting fluids contain up to 4% active sulphur in straight mineral oil.

*Prepared by the Subcommittee on Cutting Fluids. The membership of the subcommittee was as follows: O. W. Boston, General Chairman; Joseph Geschell, Chairman; M. N. Shepherd, H. L. Moir, C. B. Harding, G. F. Bowers, Floyd Fritts, A. C. Starling, W. D. Huffman, J. M. Jackson, C. L. Foreman, H. E. Martin, Raymond Haskell, W. H. Oldacre, E. M. Slaughter, Maurice Reswick, and M. W. Reynolds.

2. Sulphurized compounded oils—These oils are combinations of fatty oils, such as lard, rapeseed, degrass, sulphur, and petroleum oils.

3. Sulphurized base oils—These are concentrates containing relatively high percentages of sulphur compounds which the user blends with mineral oil to meet individual requirements.

Sulphurized oils are used extensively in broaching, gear cutting, automatic screw machine work involving threading and tapping on straight carbon or alloyed steels and hot rolled steels. They are satisfactory also for machining stainless steel, high nickel alloys, and copper.

In addition to the above, various chemicals such as phosphorus and chlorine compounds may be used in cutting fluids. Graphite, mica, white lead, and similar solids are sometimes used. (See Part II for further applications of cutting fluids for copper, aluminum, steel and zinc.

Quantity of Cutting Fluid—Best results are obtained when any of the cutting fluids are applied to the work and tool in ample quantities such as 3-5 gal. per min. for each single point tool.

Part II

Lubrication of Metals for Fabrication and Cutting

By B. H. McGar*

Aluminum—When drawing light gage aluminum, a petroleum oil having a viscosity of 100-200 seconds Saybolt at 100°F. will give satisfactory results, or a solution composed of 75% petroleum oil with a 200 viscosity and 25% lard oil with a maximum free fatty acid content of 3% may be used. On light gage difficult draws, a lubricant composed of 50% high viscosity petroleum oil and 50% lard oil having a total free fatty acid content of 3% is satisfactory. For heavy gage aluminum, use straight low free fatty acid oils.

For cutting ordinary aluminum, a solution composed of 50% kerosene, 40% lard oil with a low free fatty acid content, and 10% of a chlorinated solvent such as carbon tetrachloride or trichlorethylene is used. Attention should be called to the toxicity of these solvents and they should be used with caution. When using free machining aluminum, a compound composed of 75% low viscosity petroleum oil and 25% lard oil may be used, or 1 part of sulphur base oil compounded with 9 parts of light petroleum oil. (See also page 1315 the article on Machining Aluminum and Aluminum Alloys.)

The above lubricants may be removed from the articles in a modern vapor degreasing equipment. This may be followed by washing in a mild, properly inhibited alkaline cleaner at a temperature not to exceed 185°F., thorough rinsing in clean water, and drying.

Copper and Copper Alloys—As an aid in forming, stamping, and drawing strip brass or copper, a suitable lubricant must be used. For most operations, a 3% aqueous solution made from a good grade of soap chips will furnish an excellent lubricant. The solution should be kept slightly warm so as to prevent it from forming a gel. For more intricate operations, it is sometimes necessary to use a 3% water solution of a compound composed of approximately 30% water, 30% free fats, and 40% soap. Compounds of this general character are readily obtainable on the market.

Previous to the drawing operation, the strip brass or copper can be completely submerged in the lubricant and drained, or the solution can be applied with a swab or, better still, applied by felt rollers which pick up the lubricant and distribute it evenly over the surface of the strip as it is fed into the press. Partly formed or drawn articles are immersed in the solution and allowed to drain before again being placed in the press for redrawing.

Regardless of whether the article is to be left in the as-drawn condition or later annealed, it is good practice to wash the articles shortly after drawing to prevent red stains. The lubricant can be removed from the article in a suitable alkaline cleaner, which may be composed of a proper mixture of caustic soda, soda ash, trisodium phosphate, and sodium silicate, together with a wetting agent. Usually 3-5 oz. of cleaner are added to 1 gallon of water and used at approximately 185°F. The articles are then thoroughly rinsed in cold and hot waters and dried.

A satisfactory lubricant for cutting, drilling and tapping leaded or free cutting brasses is a light machine oil sometimes known to the trade as pale paraffin oil, having a viscosity of about 100 seconds Saybolt at 100°F. One part of sulphonated soluble oil to 10-20 parts of water may also be used. When it is necessary to machine nonleaded brasses, mixtures varying from 75-90% of machine oil and 10-25% of lard

*Assistant Director of Research, Chase Brass & Copper Co., Inc., Waterbury, Conn.

oil may be used. Copper is more difficult to machine than brass, but various satisfactory lubricants are used, such as 3 parts of this machine oil and 1 part of lard oil, or 1 part of highly sulphurized fatty oil, so-called sulphur-base or sulphonated oil and 10 parts of light machine oil. Also, a satisfactory lubricant can be made by adding materials such as tricresylphosphate to machine oil to improve the film strength. (See also the article on Machining Copper Alloys.) These lubricants may be removed in a vapor degreasing equipment using trichlorethylene, or in alkaline cleaner solutions made by using 3-5 oz. of the cleaner per gal. of water, and maintaining the bath at about 185°F. After the cleaning operation, the articles should be thoroughly rinsed and dried.

Magnesium—See the article on Machining Magnesium and its Alloys.

Nickel—See the article on Machining High Nickel Alloys for the lubricants used.

Steel—When drawing, forming or stamping soft light gage steel sheet or strip, a suitable lubricant can be compounded by adding $\frac{1}{4}$ lb. of deodorized fish oil soap to 1 gal. of water, or by using light petroleum oil that has a viscosity of 100-200 seconds Saybolt at 100°F. Satisfactory results may also be obtained by applying a heavy emulsion composed of 1 part naphthenic base soap to 4-5 parts of water.

When a deep or intricate draw is required, a solution made of 1 part of drawing compound consisting of 20-25% soap, 40-45% free fats, 35% moisture and 3 parts of water will be found satisfactory. Some operators prefer to use a solution composed of 5 parts of water and 1 part of filled drawing compound, the latter being composed approximately as follows: 15% soap; 20% filler (such as tale, fine clay, calcium carbonate, barium sulphate); 30% free fats; and 35% water.

For light drawing of medium gage sheet steel, 1 part of filled drawing compound in 2 parts of water is suitable. Also, a solution made by adding $\frac{1}{4}$ lb. of deodorized fish oil soap to 1 gal. of water may be used. When deep drawing the heavier gages, it is common practice to use filled compounds composed of 40-60% filler and 40-60% free fats without dilution. It is also possible to use straight sulphur-base oils for such operations. When selecting a lubricant for the above operations, some care and thought should be given to the subsequent operations and what type of finish will be ultimately applied to the article, as the cleaning problem may present difficulties.

High carbon and alloy steels may be cut, threaded, or milled, using various types of lubricating compounds. When heat transfer and chip removal are of primary importance the work should be flooded with a solution made by adding 1 part of soluble cutting oil to 9 parts of water. The soluble cutting oil may be composed of 15-20% naphthenic base soap and 80-85% petroleum oil of 200-500 viscosity. Various proprietary compounded oils of the chlorinated type may be also effectively used. If a smooth finish and long tool life are required, 1 part of sulphur-base oil and 9 parts of light petroleum oil may be used. A mixture of lard oil and turpentine in varying proportions is used for machining hard steel and for drilling.

When cutting and machining low carbon steel, 1 part of soluble cutting oil base and 19 parts of water is satisfactory, or 1 part of sulphur-base oil with 15-20 parts of light petroleum oil may be used. Likewise, a lubricant composed of approximately 90% mineral oil, viscosity 250 seconds Saybolt at 100°F., and 10% lard oil, maximum free fatty acid content of 3.5%, will be found satisfactory. Sometimes free fatty acid (1-5% oleic acid) is used as compounding.

The sulphur-base oil and petroleum oil can be removed from the articles by using a modern vapor degreaser. This operation is sometimes followed by cleaning the articles in a good grade of alkaline cleaner. Frequently articles that are machined with soluble oils as a lubricant are not cleaned, as the film of oil remaining acts as a rust preventative.

Zinc—Zinc may be successfully drawn in a 3-5% aqueous chip soap solution; sometimes it has been found beneficial to add to this solution a small portion of lard oil. The lubricant may be applied to the sheet zinc in any of the ways mentioned under copper and brass.

When it is necessary to machine, cut or thread zinc, a solution composed of 1 part of neutral sulphonated soluble oil base and 14 parts of water has been found satisfactory. The drawing and cutting solutions can be cleaned from the zinc articles by washing in a mild, properly inhibited alkaline cleaner made up by adding 3-4 oz. of cleaner to 1 gal. of water and maintaining the temperature at approximately 180°F. After the washing operation the articles should be thoroughly rinsed in hot and cold waters and then dried.

Cutting of Metals*

(Gas and Electric Arc)

Cutting of Metals—Gas—Gas cutting of ferrous metals is a process of preheating the material to be cut to its kindling or ignition temperature and then rapidly oxidizing it by means of a closely regulated jet or stream of oxygen issuing from a special tool called a cutting blowpipe or torch. Hence, the process is primarily a chemical one, based on the remarkable chemical affinity of oxygen for ferrous metals, when raised to or above the kindling temperature.

The chemical reaction which results when commercially pure oxygen is brought into contact with most steels or iron, at kindling point, is an active one. In the case of carbon steel, the metal is preheated to a bright red color, in daylight, reached approximately between 1400 and 1600°F. The gases supplied and the rate of progression of the cutting should be closely regulated for accurate control.

Only the metal within the direct path of the oxygen jet is acted upon. In linear cutting, or severing, a narrow race or kerf, as it is usually called, is formed, having uniformly smooth and parallel walls. Under skilled workmanship, using mechanically guided cutting torches or blowpipes, cutting tolerances as to squareness and longitudinal alignment of the cut surface may be held within close limits.

The faces or walls of the kerf, in the commonly used carbon steels, are not injured by the cutting operation. On the contrary, their strength and toughness are slightly improved. The heat effect upon the metal resulting from normal cutting operations rarely penetrates more than approximately 0.1 in. below the cut surface in any case.

In addition to the chemical reaction in cutting, there is a noticeable and helpful mechanical eroding effect produced by the kinetic energy or motive power of the cutting oxygen stream. This washes away considerable of the molten metal in unconsumed or metallic form and adds to the efficiency and economy of the process.

With this process, heavy cuts can be made with practically the same economy as cuts made in the lighter gages. Heavy sections, heretofore uneconomical to cut by any of the mechanical cutting processes are readily and smoothly cut with oxygen.

In addition to linear gas cutting or severing, several other types of controlled oxidation are in use, which employ the free burning reaction of oxygen with ferrous metals raised to kindling temperature, to provide further facilities for severing, shaping, and working with such materials. One application, known generally as "oxygen lance cutting", utilizes a relatively long section of small diameter iron pipe. The end of the pipe is ignited and kept so by a stream of oxygen flowing through the pipe. This furnishes preheat as well as free oxygen for cutting, thus forming a lance-like cutting tool which is used primarily for emergency and heavy duty cutting, such as opening up furnace tap holes.

Another application of gas cutting is known as "flame machining". This method is used primarily to surface ferrous metals in much the same way as a planer or milling machine. The cut does not penetrate through the work, as in severing or linear gas cutting.

Chemistry of Gas Cutting—Oxidation of Ferrous Metals—The oxide of iron formed in gas cutting is a black, brittle substance, identical in composition with hammer scale or magnetite ore. Its chemical formula is Fe_3O_4 . This latter substance contains a smaller proportion of oxygen than rust or red iron oxide, Fe_2O_3 . As indicated in Fig. 1, the completed equation for the oxidation reaction in gas cutting is:

Three atoms of iron (Fe) combine with two molecules of oxygen (O_2) to produce one molecule of magnetite (Fe_3O_4). In this oxidation reaction, 1593 calories per gram or 2870 B.t.u. per lb. of iron are produced, which represent the calorific energy of the iron. As the atomic weight of iron (Fe) is 55.84 and the molecular

*This article was prepared under the sponsorship of the International Acetylene Association, who appointed a special committee to handle the work. The International Acetylene Association felt that in order to do full justice to the subject, they should invite electric welding experts and users to join their committee. The full membership of the committee was as follows: C. W. Obert, Chairman, The Linde Air Products Co.; E. V. David, Air Reduction Sales Co.; L. D. Meeker, General Electric Co.; E. W. P. Smith, Lincoln Electric Co.; A. G. Wilkoff, Union Carbide Company; C. H. Jennings, Westinghouse Electric & Mfg. Co.; H. L. Maxwell, E. I. du Pont de Nemours & Co., Inc.; and W. L. Warner, Watertown Arsenal.

weight of oxygen (O_2) is 32, it follows that the relative weights of the iron and the oxygen in magnetite (Fe_3O_4) are as 167.52 is to 64.00, or as 2.618 is to 1. Or, expressed otherwise, 1 lb. of oxygen will oxidize or consume 2.618 lb. of pure iron. Oxygen, at 70°F. and 1 atmosphere pressure, has a volume of 12.07 cu.ft. per lb. and pure iron weighs 0.285 lb. per cu.in. Based on these constants, the following data may be computed:

- 1 lb. oxygen will oxidize 2.618 lb. or 9.186 cu.in. of pure iron.
- 1 cu.ft. oxygen will oxidize 0.217 lb. or 0.761 cu.in. of pure iron.
- 1 lb. of pure iron requires for oxidation 0.382 lb. or 4.610 cu.ft. of oxygen.
- 1 cu.in. of pure iron requires for oxidation 0.109 lb. or 1.314 cu.ft. of oxygen.

In actual gas cutting, the iron or steel removed from the kerf is, as already noted, not entirely oxidized or consumed by the oxygen, but, due to the eroding effect of the cutting oxygen jet, about 30-40% of the metal is washed out of the cut, as unconsumed or metallic iron. Owing to this fortunate circumstance, it is not uncommon to obtain satisfactory cuts with a cutting oxygen consumption of even somewhat less than one cu.ft. of oxygen per cu.in. of material removed from the kerf. This, as may be seen from the above data, is more than 30% better than the theoretical figure, based on chemical reaction alone.

Carbon steels contain such elements as carbon, manganese, and silicon in combined form but in proportions that have little or no influence on the oxidation of the metal in gas cutting. These are oxidized or dissolved in the slag without interfering with the progress of the cut. However, certain alloy steels contain chromium, nickel, and other elements in sufficient amounts to have a marked retarding effect on the oxidation reaction. The uncombined or graphitic carbon in cast iron has a similar influence. Such materials are harder to cut with gas and require special technique.

Combustion of Fuel Gases—A number of higher flame temperature fuel gases have been employed for cutting ferrous metals, with varying degrees of success. The more important of these are: Acetylene, hydrogen, city gas, natural gases, coke oven gas, ethylene, and the lighter petroleum distillates, including methane, ethane, propane, and butane. Table I gives combustion constants for certain of these fuel gases.

Table I
Combustion Constants of Fuel Gases

Name of Gas	Chemical Equation for Complete Combustion	Heat Value B.t.u. per cu.ft.	Flame Temp. With Oxygen, °F.
Acetylene.....	$C_2H_2 + 2\frac{1}{2}O_2 = 2CO_2 + H_2O$	1433 net	6300
Hydrogen.....	$H_2 + \frac{1}{2}O_2 = H_2O$	275.1 net	5400
City gas.....	Typical mixture	300-800 net	4600
Natural gas.....	Typical mixture	800-1200 net	4600
Coke oven gas.....	Typical mixture	500-550 net	4600
Methane.....	$CH_4 + 2O_2 = CO_2 + 2H_2O$	913.8 net	5000
Ethane.....	$C_2H_6 + 3\frac{1}{2}O_2 = 2CO_2 + 3H_2O$	1631 net	5100
Propane.....	$C_3H_8 + 5O_2 = 3CO_2 + 4H_2O$	2309 net	5300
Butane.....	$C_4H_{10} + 6\frac{1}{2}O_2 = 4CO_2 + 5H_2O$	2999 net	5300
Ethylene.....	$C_2H_4 + 3O_2 = 2CO_2 + 2H_2O$	1530 net	5100

Aside from hydrogen all of these fuel gases are hydrocarbons and, as shown in Table I, give off carbon dioxide (CO_2) and water vapor (H_2O) as products of complete combustion. They may be burned in different manners, but, when used for gas cutting, the combustion is made to take place in the way that will develop maximum flame temperatures. For quick starting and rapid progress of a cut hot preheating flames are a prime essential. This condition is fulfilled by designing cutting torches or blowpipes to burn the fuel gases on the Bunsen principle and to premix commercially pure oxygen instead of air with them before combustion. The substitution of oxygen in place of air for the primary combustion results in a notable increase of flame temperature of the fuel gas, as the nitrogen, constituting nearly four fifths of the air, must not be heated by the flame when oxygen is used. In the case of acetylene, a hot and short flame, with an easily distinguished, bright inner cone is produced, the hottest point being at the inner cone tip. Hydrocarbon gas flame structures are of a complex nature, with a multiplicity of cones, caused by the successive chemical reactions taking place in different stages.

Depending on the ratio of oxygen to fuel gas in the mixture, the characteristic of the flame produced may be carburizing, neutral, or oxidizing. The neutral flame results when just sufficient oxygen is supplied to complete the primary combustion in the inner flame cone, giving carbon monoxide (CO) and hydrogen (H₂) as products. Neither of these two gases has any tendency to carburize or oxidize molten metal, but are neutral to it. Regardless of the amount of primary oxygen supplied, complete combustion in the inner flame cone is impossible since, at such extremely high temperatures, carbon dioxide and water vapor are unstable and dissociate or revert back in part to carbon monoxide, hydrogen and oxygen. This dissociation limits maximum attainable oxy-fuel gas flame temperatures, which otherwise might go much higher.

Maximum flame temperatures are obtained with strongly oxidizing flames, which type, therefore, are generally used for gas cutting. Oxidizing flames preserve the general appearance of neutral flames, but their inner cone is shorter, "necked in" on the sides and not so sharply defined. Due to dissociation, the products of the primary combustion in the inner cone of excess oxygen flames consist of carbon monoxide, carbon dioxide, hydrogen, water vapor, and free oxygen, in proportions depending upon the amount of excess oxygen premixed with the fuel gas.

The secondary combustion of the fuel gas takes place in the outer or envelope flame. Here, any carbon monoxide or hydrogen contained in the primary combustion products complete their combustion to carbon dioxide and water vapor, respectively, as the lower temperature is insufficient to cause dissociation of these latter compounds. The necessary oxygen required for completing the secondary combustion in the envelope flame is taken from the surrounding air by diffusion into the zone.

Table II gives optimum gas ratios and equivalent volumes of oxygen and acetylene, city gas, natural gas, and propane required for gas cutting the same work at the same speed.

Table II
Equivalent Fuel Gas and Preheating Oxygen Volumes for Cutting

Name of Fuel Gas	Optimum Ratio Oxygen to Fuel Gas	Gas Consumption Preheating Oxygen	Cu.ft. per hr. Fuel Gas
Acetylene	1.7 -1	17	10
City gas	0.75-1	56	75
Natural gas	2.0 -1	56	28
Propane	4.5 -1	54	12

The data in Table II applies only when each fuel gas is utilized at its maximum efficiency. In practice it is difficult for the operator to adjust the gas ratio of other gases than acetylene to even approximately correct values. Because there is no definite starting point, such as the neutral flame in the case of acetylene, even an experienced operator frequently adjusts the gas ratio of the flames utilizing other fuel gases to much higher gas ratios than the best values indicated by Table II. Obviously this involves the use of much more oxygen than otherwise would be required. With acetylene, the change in the size and brilliance of the flame when adjusted to the oxidizing side of the neutral flame is great enough to make it quite unlikely that any operator will employ appreciably higher oxygen-acetylene ratios than necessary.

Furthermore, when certain other fuel gases are used, the oxygen requirements for the cutting jet are also greater than when acetylene is used. This is particularly true where the preheating gas consumptions are large and the resulting gases of combustion are sufficient to pollute the cutting oxygen jet. In such cases a noticeable deterioration in the cutting efficiency may ensue.

Combustion of Acetylene—As acetylene is the most widely used fuel gas for cutting, its combustion will be described in greater detail. Table I and III show the chemical equation for the complete combustion of acetylene to be:

In other words, 1 molecular volume of acetylene unites with 2½ molecular volumes of oxygen to form 2 molecular volumes of carbon dioxide and 1 molecular volume of water vapor, with a liberation of 542,700 B.t.u. of heat.

Most hydrocarbons are exothermic, generating heat during formation and absorb-

ing the same amount of heat during combustion. But acetylene is highly endothermic, absorbing heat during formation and liberating it again on burning or decomposing. The endothermic heat liberated by acetylene is in addition to that produced by the combustion of its component elements. The total heat generated is given in Table III.

Table III
Heat Produced by Complete Combustion of Acetylene

	Reaction Formula	B.t.u. Per Molecule	B.t.u. per Cu. Ft. at 60°F. and 1 Atmos.	% of Total
Endothermic	$C_2H_2 = 2C + H_2$	86,600	228	15.9
Carbon	$2C + 2O_2 = 2CO_2$	352,000	928	64.8
Hydrogen	$H_2 + \frac{1}{2}O_2 = H_2O$	104,100	277	19.3
Total heat of combustion.....		542,700	1,433	100.0

Acetylene contains the highest percentage of carbon (92.3% by weight) of any common gaseous hydrocarbon compound. This, coupled with its exceptionally large endothermic heat, gives it the highest flame temperature by a wide margin of any known fuel gas.

Oxygen Purity—High purity oxygen is essential for rapid and efficient cutting. Even a small percentage of impurities in oxygen causes a great loss in its cutting quality. Tests of machine cutting 12 in. mild steel billet in the laboratory, under identical conditions, using oxygen from 97.5-99.5% pure, gave results summarized in Table IV. The results demonstrate clearly the importance of high purity oxygen for cutting.

Table IV
Effect of Oxygen Purity on Consumption

Purity, %	Oxygen Consumption	
	Cu.ft. per Linear Foot Cut	Increase, %
99.5	45.5
99.0	49.5	8.8
98.5	55	20.9
98.0	63	38.5
97.5	73	60.5

Effect of Gas Cutting on Steels—In gas cutting, a slight depth of metal immediately adjacent to the cut face is raised to a bright red heat or considerably above the critical range. As the cut progresses, the steel cools again through this range. The speed of cooling is dependent upon the heat conductivity of the surrounding metal, radiation losses, and the fact that the heat is applied only momentarily at any given point, the cutting torch being kept in constant motion while cutting. Where the steel being cut is at room temperature, the rapidity of the cooling is sufficient to actually have a chilling or quenching effect on the cut edges, particularly in the case of heavier cuts involving large masses of cold metal.

When polished and etched specimens are taken from gas cut edges and examined under the microscope, the material is found to be altered when compared with the original metal. However, the change is largely a physical one, concerned with crystalline grain structure. The normal pearlitic steel is transformed into one or more of several structures ranging from spheroidized carbides in the ferrite to the harder constituents, depending upon the particular chemical composition of the steel cut and the rate of cooling following the cutting operation, as well as the carbon content and the alloying elements present. Also, an alteration in grain dimension at the gas cut edge is induced due to the intensity of the heat developed by the cutting to render the grains either larger or smaller than the unaffected grain behind the cut edge.

Low Carbon and Mild Carbon Steels—Gas cutting of carbon steels at normal temperatures containing less than 0.35% carbon is not detrimental. Indeed, gas cut edges of such steels are suitable for any uses where edges prepared by any of the mechanical methods of severing, as for example planing, milling, shearing, friction sawing and grinding, are employed. Gas cut edges are adapted to applications involving stresses, such as mechanical calking and holes in which tubes are to be

expanded or rivets driven. Clean, smooth gas cut edges of low or medium carbon steel plates or forgings actually have physical properties that render them superior to sheared, planed, or otherwise mechanically prepared edges.

An investigation of the conditions which develop when the fusion welding process is applied to gas cut edges, conducted a few years ago by the A.S.M.E. Boiler Code Committee, produced such conclusive results that all restrictions in the Boiler Code pertaining to welding on gas cut surfaces were removed. The wording of the Code requirement, which was adopted in 1935 for incorporation in the Power Boiler and Unfired Pressure Vessel Sections, is as follows:

"Preparation for Welding—The plates may be cut to size and shape by machining or shearing, or by flame cutting if the carbon content does not exceed 0.35%. If shaped by flame cutting, the edges must be uniform and smooth and must be freed of all loose scale and slag accumulations before welding. The discoloration which may remain on the flame-cut surface is not considered to be detrimental oxidation."

Where edges are gas beveled to form a vee for welding, and later are welded together, either by oxy-acetylene blowpipe or electric arc, the heat of the welding operation acts to dissolve all previously formed marginal structures and operates to anneal the metal for an appreciable depth below the cut surface. Any change in structure that the preceding cutting may have produced in and adjacent to the cut surface is therefore obliterated.

Tests of flame cut edges of low and medium carbon steels to determine their physical properties, such as hardness, microstructure, resistance to impact, and ductility have shown that they are satisfactory for almost any type or character of mechanical treatment or service.

Higher Carbon and Alloy Steels—Gas cutting of higher carbon and alloy steels, particularly at room temperature, may produce a thin layer of hard material on the cut surfaces which may not be sufficiently ductile to withstand the stresses set up in cooling without cracking, or imposed by the subsequent use of the part cut. As the steel is momentarily highly heated by the torch at the cut edges it tries to expand but is restrained by the adjoining cold metal. The action called "upsetting" results. Later, when cooling occurs, contraction of the upset metal may develop severe stresses in tension along the cut edges. With these steels, the ductility may

not be sufficient to prevent incipient cracks and checks which can prove dangerous in service, as they are apt to develop into large fractures.

Preheating and Annealing—Experience has shown that if these higher carbon and alloy steels are preheated and in certain cases annealed after ward, no cracks will occur on the cut edges. Naturally, with the adjoining metal preheated, the difference in expansion between it and the metal heated during cutting is less and "upsetting" is greatly reduced or eliminated.

Certain steels may be preheated to as high as 1000°F. or more for gas cutting. However, care must be exercised not to carry the preheating too far, as the metal may develop too great an affinity for the cutting oxygen jet at elevated temperatures, thus

Fig. 1—Chemistry of oxy-acetylene cutting.

causing it to act erratically and prevent proper control of the cut. Special precautions should be taken in cutting particularly thick preheated sections to see that the work is done as quickly as possible after the piece has been withdrawn from the

furnace. This avoids having the interior considerably hotter than the metal at the surface, which condition may arise if the piece is allowed to partially cool in air before cutting. In the latter case, the oxygen jet may start its penetration without much difficulty, but upon entering the interior of the section fail to go through and cause a flare-up in the cutting. This stoppage is due to the hot center, which oxidizes so readily that a cavity or pocket may form on the inside of the piece. Where this occurs, a slight lowering of the cutting oxygen pressure often will be found to clear up the trouble.

To obtain the most efficient use of the oxygen and, at the same time, leave the steel in the best condition, a preheat temperature of 500-600°F. ordinarily should suffice for carbon steels. The additional expense that accompanies preheating is compensated for by the more rapid rate at which preheated steel can be cut.

Annealing completely restores the original pearlitic structure of the steel at the cut edges, wherever this may be desired, and removes any internal stresses set up in the metal. If carried out, it should be done immediately after cutting. Annealing temperatures suitable to the type of steel in the piece are employed. These temperatures are ordinarily in the neighborhood of 1250-1450°F. Annealing time depends on the grade of the steel, its thickness and shape.

When preheating has been used before flame cutting, the majority of steels do not require annealing. This applies to the steels which harden only when rapidly quenched from temperatures above the critical point. However, the air hardening steels must be annealed or cooled very slowly after cutting, if preheated. The low alloy, high strength steels of nickel, silicon, and manganese grades usually are in this category. For these it is essential that the postheating does not exceed the critical point.

Flame Softening—Flame softening is a localized and progressively applied oxy-acetylene heat treatment, similar in its physical aspects to flame hardening, but directly opposed in its objective. The results of flame softening are similar to those obtained by preheating in a furnace, but the effect can be restricted to a small area and the process is comparatively simple and economical.

Flame softening can be applied in any one of several ways. In some cases it is of advantage to preheat the metal locally prior to cutting; in others the heat treatment is applied after cutting, either directly to the cut surface or to the metal adjacent to the cut. The most effective and economical method to employ depends upon the dimensions and composition of the metal to be treated, as well as upon such factors as the service for which the metal is intended and the results sought.

Mechanical Effects of Gas Cutting—Properly performed gas cutting on carbon and low alloy steels produces accurate results. Top and bottom edges of cut are sharp and width of kerf uniform. Surfaces of cut may be smooth and square and be produced without "drag" lines. Precision obtainable depends upon: (1) The cutting equipment and procedure employed. (2) The cutability of the material. Other mechanical effects of gas cutting result from warping, due to the expansion and contraction of the steel in heating and cooling. When a part is locally heated, as in gas cutting, it may warp, unless: (a) Its stiffness or cross sectional strength is sufficient to resist the forces set up. (b) It is held in place by clamps or weights while cutting and cooling. (c) It is multiple cut simultaneously or in rapid succession about its neutral axis, thus equalizing the forces set up and neutralizing their effect. (d) The cutting operation is immediately and progressively followed by rapid cooling or quenching with a suitable medium.

Plates of $\frac{1}{2}$ in. thickness and above are seldom warped or buckled by gas cutting, unless unduly long and narrow. In such simple operations as cutting off rods, bars, rails, piping, structural shapes, and similar lengthy materials, warpage is not involved. So-called "skip-cutting" is frequently used in splitting narrow materials, such as flat bar stock and structural I-beams and channels to prevent warpage. In this method, the cut is made to skip at intervals, depending on the work, leaving a series of uncut sections along the line of cut, each about $\frac{1}{2}$ in. to 1 in. long. These uncut ligaments hold the material in line until cooled, whereupon they are cut through to separate the parts. Sometimes simultaneous cuts, made with two or more torches, moved together along parallel lines, are used to eliminate warpage, increase production and reduce costs. For some operations, such as beam splitting, water quenching is an effective check to warpage. Where great accuracy is demanded in over-all dimensions of larger cut parts, suitable correction factors must be applied in making the cutting layout, particularly where the steel is preheated.

Gas Cutting Equipment—Gas cutting equipment consists ordinarily of the cutting torch or blowpipe with separate cutting tips of different sizes, oxygen and fuel

gas hose with connections, oxygen and fuel gas pressure regulators, and gas cylinders. The pressure regulators usually are equipped with cylinder and working pressure gages. Cutting oxygen regulators are designed especially to deliver oxygen in large volumes and at higher pressures and, hence, usually are fitted with 400 psi. working pressure gages.

Where larger quantities of oxygen are required, oxygen cylinders often are manifolded. Acetylene generators, rather than cylinders, are used where the consumption justifies it. For such installations, distribution pipe lines frequently are employed to carry both gases to the various points of consumption throughout the

premises. For machine gas cutting, the torch is held and operated mechanically, but its essential features and the accessory equipment remain unchanged. To assure safety and efficient results, the manufacturer's instructions for setting up and operating the equipment should be followed closely in each case.

Gas Cutting Processes—Flame Cutting—The primary use for gas cutting is that of severing. With this process, the cut is made through the material as at (a), Fig. 2, leaving the cut edges in a plane usually at 90° to the surface of the part cut. The cutting tip preferably is held perpendicular to the surface, as shown, although in certain cases it may be tilted somewhat along the line of cut. For bevel cutting, the tip is tilted to the required angle or a bent tip is used, but the cut still penetrates through the material. These processes are widely known as "Flame Cutting."

Fig. 2—Flame cutting.

Flame Machining—This process utilizes the same fundamental principle of chemical reaction, but the cutting oxygen stream is made to impinge on the work at a more or less acute angle, as at (b), Fig. 2; in some cases almost tangentially. The cut is not permitted to penetrate through the work, as in severing, but is restricted to removal of a predetermined depth and width of material from the surface by oxidation, as indicated. The various gas cutting processes are classified in Fig. 3.

Fundamental Principles of Flame Cutting—Drag and Quality—In flame cutting, the cutting oxygen jet usually enters the cut in line with the cutting oxygen orifice axis (a) in Fig. 2. After traversing about one-half the thickness of the cut, however, it may curve backward in a direction opposite to the travel (Fig. 1). When this occurs, the amount by which the oxygen jet falls behind the perpendicular in passing through the material is known as the "drag" of the cut. Faint markings or ridges called "drag lines" left on the face of the cut enable this to be measured, as shown in Fig. 1. In heavy cuts, these drag lines are more pronounced. Cuts with short or negligible drags are known as "high quality" cuts, while those with long drags are termed "low quality" cuts.

Cutting studies have shown that: 1. As the drag is decreased the oxygen consumption is increased. For very short drags, a slight decrease in drag length can be procured at the expense of increased oxygen consumption. 2. Except for low cutting speeds, a certain minimum length of drag is characteristic of a given tip and speed regardless of the operating pressure (or the oxygen consumption). 3. An increased drag may result if an attempt is made to obtain a drag shorter than the minimum by increasing the operating pressure beyond that at which the minimum drag is obtained.

In considering the economies of flame cutting, therefore, it is essential to determine how short the drag must be to fulfill the requirements. If it is too long, an uncut final corner will result and this is usually not permissible. Straight line cuts frequently may be made with considerable drag, without much detrimental effect, as the drag lines lie within the plane of the cut and do not prevent both top and bottom edges of the cut from being left clean and sharp. This procedure saves considerable oxygen. It is also applied in scrap cutting where cut quality is

nonessential, so long as severing is accomplished. However, in shape cutting, when rounding curves or corners, less drag is permissible, as the bottom contour of the cut will tend to come out differently from the top, with the edges not square. Such cuts must be made of small drag, high quality type. They require a good deal more oxygen than cuts with long drags which barely penetrate the material. Precision machine flame cuts are necessarily of high quality.

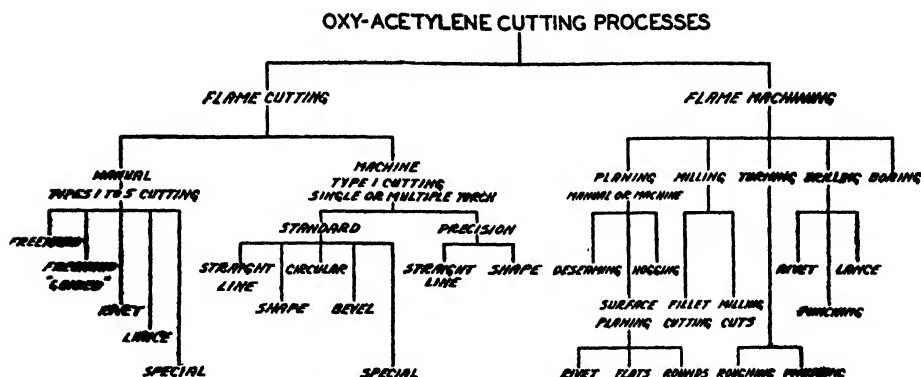

Fig. 3—Classification of gas cutting processes.

Satisfactory Commercial Flame Cuts—These must fulfill the following requirements: A. A sufficiently short drag; that is, the line markings on the face of the cut should approach the straight up-and-down condition. Drag should not be long enough to prevent the final corner being cut and the piece from dropping. B. The sides of the cut should be sufficiently smooth—not grooved, fluted or ragged. C. There should be no firmly adhering slag on the bottom of the cut, as this requires an appreciable expenditure of labor for its removal. With proper adjustments, only loose slag or none at all is obtained. D. The upper and lower edges of the cut should be sufficiently sharp to meet the requirements of the particular job. E. The cost must be moderate.

The following conditions are necessary to obtain smooth cuts: 1. Suitable cutting tip, with correct size cutting orifice and proper degree of preheat. 2. Proper oxygen and fuel gas pressures. 3. Correct cutting speed. 4. Uniformity of torch movement. 5. Uniform oxygen and fuel gas pressure regulation. 6. Smooth and uniform bore and proper type of cutting orifice. 7. Cleanliness of orifice exit. 8. Cleanliness of preheat holes. End of tip must be kept free from adhering slag. 9. High purity oxygen. 10. Proper angle of incidence of the cutting oxygen stream to the upper edge.

Selection of Cutting Tip or Nozzle—A wide variety of cutting tips or nozzles of different styles and sizes is available for flame cutting. They provide for cutting various thicknesses of most ferrous materials, and for different surface conditions, such as clean, painted, rusty, or scaly surfaces, as well as for a variety of special types of work. The thickness of the material to be cut governs the diameter of cutting orifice of the tip to be selected. The condition of the surface and composition of the metal determine the intensity of preheat flames which should be used. Rusty or scaly surfaces often are cleaned or "descaled" along the line of cut before cutting, by cracking the scale loose either with the torch preheating flames, or mechanically with scrapers or chipping hammers.

Starting Flame Cuts—In most cases, flame cuts are started at the edge of the piece. The cutting torch is held so that the ends of the preheating flame inner cones just clear the surface of the material. When a spot of metal at the top of the edge has been heated to a bright red, the cutting oxygen jet is turned on. The metal in the immediate path of the cutting jet oxidizes and, as the torch is moved slowly and steadily along the line to be cut, separation is effected. In flame cutting ordinary steel, the tip should be held vertically at a correct distance above the surface and advanced uniformly at the proper speed, without wavering.

Piercing Holes—In starting a flame cut in the metal away from the edge, or in piercing a hole, more time usually is consumed in bringing the spot to the kindling temperature, than with edge starting. When a spot has been heated to a bright

red, the torch is raised about $\frac{1}{4}$ in. above the normal position for line cutting and the cutting oxygen turned on slowly. As soon as the work is perforated, the torch is lowered again to the normal height above the surface and any further cutting that may be required is carried on. Drilled holes are used for certain work, particularly to form a straight, smooth starting edge for a heavy internal cut.

Cutting Rounds—When cutting round bar steel, gas pressures are set for the maximum thickness, or diameter, and the cut is started at the side. As the cut progresses, the torch is raised to follow the circumference. Starting is facilitated by nicking the round with a chisel to create a burr at the point where the cut is to begin, for the oxygen to take hold more easily.

Heavy Cutting—In heavy cutting, the greatest care must be exercised in selecting the proper operating pressure. Not only is the range of suitable pressures considerably narrower for the heavier cuts, but the pressure drops through the hose line connections and the torch becomes rapidly larger with the increasingly greater oxygen flows demanded for heavy cutting. Variations in the quality of the steel are also more important in the case of heavy cutting.

Considerable skill must sometimes be exercised in starting a heavy cut to completely sever the initial lower corner and avoid pocketing of the cutting oxygen stream in the lower portion of the cut. It is essential that the front edge of cut be very clean, particularly the lower portion of the front face. The axis of the tip should be aligned with the front edge of the material by turning on the cutting oxygen stream with preheating flames burning to render it visible. In starting the cut the movement of the torch should be retarded just long enough to allow the cutting stream to actively attack the material throughout almost its entire depth. Then the torch is permitted to proceed normally. If the piece is very heavy, the lower portion of the front face is sometimes heated with a large welding flame. In certain cases, starting is facilitated by first undercutting the forward edge of the material with a hand cutting torch, Fig. 4. Unless done by an experienced operator, however, poor and ragged cuts may be obtained by this method.

Care is also often required in completing the final corner of heavy cuts. A slight retardation of the forward movement of the torch is desirable here as well, but this must be properly carried out.

Scope of Flame Cutting—Thickness—With standard cutting torches not assisted by oxygen lances, present limits of penetration are about 24 in. for manual cuts and 33 in. for machine cuts. But thicker sections have been cut by making a non-penetrating cut in one side and then turning the piece over and making a second cut to join the first. Particularly for free hand flame cutting, the upper limit depends largely upon the skill and steadiness of the operator. With oxygen lances it is possible to penetrate through practically any thickness of metal.

Materials—Almost any ferrous material can be gas cut. However, certain steels contain sufficient alloying elements to offer considerable resistance to the process. The uncombined carbon in cast iron has a similar effect. For such materials, special flame cutting techniques, as described later, must be applied. Oxygen lances permit penetration of practically any material, ferrous or otherwise.

Cross Cut Tolerances—Where the torch is held firmly and advanced at uniform speed, as in machine flame cutting, cross cut tolerances can be kept within narrow limits. In ordinary steel of 6 in. thickness, cut surfaces can be held true as to cross sectional squareness to within $\frac{1}{16}$ in. Cuts in thinner sections can be held within proportionately smaller limits. The degree of longitudinal precision of a machine cut depends on the trueness of the guide rails of the cutting machine, the clearance of the operating mechanism and the regularity of the propelling unit. Machine cuts can be made so smooth and square and have such sharp edges that they require no further finishing of any kind.

Bevels—Angular or bevel flame cuts are accomplished by inclining the torch and tip sideways to the desired angle, or by using a bent tip. Such cuts may be made either by hand or machine, both in straight or irregular lines and with the same depth range as in normal right angle cutting. The usual angular limits of bevel and straight faced fillet cutting are indicated in Fig. 5.

Shapes—Straight lines, circles or contours of the utmost complexity are flame

Fig. 4—Undercutting as an aid in starting a cut.

cut with equal ease, by either mechanical or hand guided torches. Flame cutting, in sharp contrast with most machine tool processes, has practically unlimited flexibility in this respect, Fig. 9.

Multiple Torch Cutting—In many applications of machine flame cutting, as many as six torches are used to cut a like number of identical shapes simultaneously. Concentric circles for flanges and the like often are cut in one operation, with two or more torches.

Fig. 5—Limits of bevel and fillet cutting.

Stack Flame Cutting—In addition to cuts made through a single thickness of material, flame cuts are made through several thicknesses simultaneously. This operation is known as "stack flame cutting" and offers a means of cutting numerous shapes simultaneously with a single torch, instead of employing multiple torch cutting.

The plates in the stack should be clean and flat, with edges in alignment where the cut is started. Their number should vary with the thickness of individual plates, to keep stack thickness within proper limit. They should be firmly clamped together as nearly as possible along the line of cut. In stack flame cutting thin plates, a "waster plate," having sufficient rigidity to lie flat while the cut is being made, usually is clamped on to prevent the top thin plate from buckling with the heat. It serves also to maintain ignition in the cut by its own combustion, thereby facilitating the speed of cutting in this kind of work.

Flame Cutting Techniques—Several different flame cutting techniques have been developed, for performing various cutting operations and for cutting different grades of ferrous metals. The International Acetylene Association in its Oxy-Acetylene Committee Publication, Section I, entitled "Oxy-Acetylene Cutting" defines five distinct flame cutting techniques. These are typified from the standpoint of flame movement in Fig. 6 and may be described as follows:

Type 1 Flame Cutting—This is the simple progressive type, universally used for

Fig. 6—Types of cutting techniques.

Fig. 7—Relationship between thickness, metal removed, and oxygen consumed.

carbon steels and other easily cut ferrous metals. The cut proceeds freely and regularly in a line and at the will of the operator. The technique consists in first preheating a spot to kindling temperature (1400-1600°F.) with the several small

preheating flames surrounding the cutting oxygen orifice. The cutting oxygen is then turned on and the cut started. Theoretically, preheating should be really necessary for starting only. In practice, however, preheating flames are maintained throughout the cutting operation, to insure continuity of cutting and high speed. Manipulation of the torch is merely that of holding it at correct height above the surface and advancing it at proper uniform speed along the line of cut, Fig. 6. The high velocity of the cutting oxygen stream confines it to a narrow path and holds its oxidizing action to within close limits. This makes accurate control possible. In practice, a considerable portion of the metal removed from the kerf is blown out in molten metallic form, unoxidized. This is particularly true with heavier cuts. Fig. 7 illustrates the relationship between thickness, metal removed and oxygen consumed in Type 1 flame cutting.

Type 2 Flame Cutting—Commercially, this is known as oxygen lance cutting. Practically all ferrous metals and many other materials can be cut or pierced with the oxygen lance. The lance ordinarily consists simply of a length of $\frac{1}{4}$ or $\frac{3}{8}$ in. I.D. size black iron pipe, with a globe valve on one end, connected to an oxygen hose, regulator and cylinder or manifold, so that only oxygen flows through the lance pipe.

Similar to Type 1 flame cutting, a spot is first preheated to kindling temperature, usually with a welding torch with large tip. Then the end of the lance is brought against the heated area and oxygen at about 40-50 psi. turned on. This oxidizes the metal and sufficient heat is produced to continue the cut or hole with oxygen alone, without oxy-fuel gas flames to facilitate the progress. The end of the lance is held in the cut or hole, so that the cutting oxygen stream emerges at the point of cutting or oxidation. This heats the end of the lance pipe, causing it to burn also. As the operation proceeds, the lance is consumed, ultimately requiring replacement by a new length of iron pipe. Oxidation of the lance itself requires only a minor portion of the oxygen consumed, while the heat of the burning lance assists the cutting.

Once started, the oxidation reaction is vigorous. It may be further intensified, if desired, by using a lance pipe of greater wall thickness, or by inserting one or more steel rods in the pipe. The thicker pipe and rod inserts both furnish additional fuel and heat, while the rods decrease the area of the effective opening in the lance pipe, thereby imparting greater velocity to the oxygen stream and increasing its eroding effect.

Oxygen lance cutting acts to extend the depth penetration range of standard cutting torch operations. It is seldom used alone but as an aid to Type 1 flame cutting in severing thick or heavy masses of metal. However, under proper conditions and set-up, oxygen lances can be employed independently. With various modifications, they are used for flame cutting large sections of cast iron, steel and other materials. For example, they serve to burn holes in salamanders and ladle chills, in which, after cooling, dynamite is inserted and exploded for final demolition. The opening of tap holes in blast and open hearth furnaces with the oxygen lance has become standard practice. In this operation, a spot of metal in the tap hole and the end of the lance pipe are both heated red hot with an oxy-acetylene welding torch. Oxygen is then allowed to flow through the pipe and impinge on the hot metal which is quickly pierced, allowing the molten metal to flow out.

Lancing usually consumes more oxygen per pound of metal removed, than other types of flame cutting. This, however, is offset by the greatly increased value of the cutting service as compared with other methods that can be used for such work. Obviously, the surface produced by Type 2 flame cutting, or lancing, is not as smooth as is obtained with Type 1 flame cutting. Nevertheless, surprisingly accurate holes can be pierced with the lance. Oxygen lance cuts should be made so that the slag and molten metal can flow out of the cut freely by gravity, wherever possible.

Type 3 Flame Cutting—This technique was developed especially for cutting cast iron. Considerably more preheat is used than in Type 1 flame cutting, both in starting and maintaining the cut. In addition, a definite flame oscillation is resorted to, which is necessary for cutting the cast irons, particularly those possessing carbon in the uncombined or graphitic state, as this resists flame cutting. The sidewise motion or oscillation of the flame is roughly in the form of half circles or new moons, advancing in short and regular intervals, as shown in Fig. 6, Type 3 (Heavy) when cutting heavy cast iron. A slight modification of the flame oscilla-

tion, also shown in Fig. 6, Type 3 (Thin) has been found more advantageous for cutting thin cast iron.

The resulting cut, therefore, may be termed a "worked cut," for the cast iron originally in the kerf has, in reality, been "worked out" by the oscillating technique. The latter, if regularly maintained, causes a constant stream of slag and molten metal to flow through the kerf, preheating the base metal in the kerf and preparing it for further oxidation and displacement as the molten products are removed. The cut naturally is somewhat rougher than a Type 1 flame cut, more of the metal having been removed by the mechanical eroding effect of the cutting oxygen

Fig. 8—Flame for Type 3 Cutting.

Fig. 9—Examples of shape cutting.

jet. Due to the wider kerf produced, more metal must be oxidized and oxygen and acetylene consumptions are greater than for Type 1 flame cutting.

Highly carburizing preheating flames are used in Type 3 flame cutting of cast iron; that is, the flames are adjusted to carry a considerable excess of acetylene, which appears as a long whitish feather in the flames beyond the small brilliant inner flame cone, Fig. 8. The length of the excess acetylene streamer should be approximately equal to the thickness of the cast iron. This flame adjustment aids in maintaining preheat in the cut, as the excess acetylene combines with cutting oxygen beyond the tip.

Type 3 flame cutting, or cast iron cutting, appears to be limited at present to demolishing castings, usually in basements or other inaccessible locations where they must be broken up before removal, or otherwise reduced in size, and to making alterations and repairs to machinery.

Type 4 Flame Cutting—For severing the so-called stainless steels, which resist ordinary techniques, a distinctive cutting technique, utilizing a different flame motion or oscillation from Type 3 flame cutting, has been developed. Here also, the flame is moved continually while cutting, but in a reciprocating manner in short strokes back and forth along the line of cut, Fig. 6, instead of sidewise. In starting a stainless steel cut, preheat is applied along the entire face or leading edge of the cut, from top to bottom, until it has been brought to a bright red color, in addition to preheating the usual spot at the top edge. Then the cutting operation

is started and progressed through the part by the forward and backward reciprocating motion already described, advancing the cut in short forward increments each time.

As in Type 3 flame cutting, the maintenance of a steady stream of liquid slag and molten metal is essential for a successful cut. Slag erosion is probably as important as any other single factor in cutting stainless steels. It determines the degree of uniformity in which cutting in these metals is attainable. Naturally, Type 4 cutting leaves a rough surface, calling for subsequent machining or grinding if a smooth finish is desired.

Type 5 Flame Cutting—This technique is developed around the use of metals of relatively high cutability to aid in the cutting of metals of lower cutability, similarly as fluxes are used in certain welding operations to increase the fusibility of refractory oxides. Different forms of this technique are employed, which, in the main, resort to cover, or cover and intermediate plates, known as "waster plates" of low carbon steels, placed as jackets or interlaminations between the resistant metals. These waster plates act to initiate good cutting conditions and relay them through the stack. The top and bottom plates sometimes are used merely to produce sharp cut edges in parts otherwise readily cuttable. In stack flame cutting, already described, their principal use may be for clamping a stack of thin plates firmly together. For certain operations, a light bead of low carbon steel is arc welded to the plate surface along the line of cut and the cut is made through this bead, which assists the cutting action in resistant metals. The bead is consumed in the cutting.

Another form of Type 5 in flame cutting employs a low carbon steel rod or bar at the point of cutting to supply additional heat and slag to a cut in a resistant material, thereby supplementing the work of the cutting torch. The bar or rod can be moved at the will of the operator, to be available at or adjacent to the critical point of cutting. Iron filings also can be used. This method often enables castings or resistant materials to be cut quite readily.

Any of the previously described flame cutting techniques may be employed in Type 5 flame cutting, depending on the resistance of the material to the process.

Table V
Effect of Alloying Elements on Gas Cutting of Steel

Element	Effect
Aluminum	Aluminum content does not hinder flame cutting. However, an aluminum content of 10-15% resists flame cutting either hot or cold, except where special technique is used.
Carbon	Carbon in unalloyed steels up to 2% permits of flame cutting by simple progressive procedure (Type 1 technique). However, steels containing more than 0.30% carbon should be preheated to 500-600°F. before cutting, or heated, after cutting, before the cut surface cools to normal temperature to prevent hardening and cracking at edges. Quality of cut is affected by both amount and form of carbon content. Graphite and cementite (Fe_3C) tend to hinder cutting, but cast irons containing 4% carbon are cut successfully by special technique (Type 3).
Chromium	Chromium contents up to 1½% have no adverse effect. Steels with 4-6% chromium also may be cut by Type 1 technique, provided low intensity carburizing preheating flames are used. Where the chromium content is 10% or more, special cutting technique is required to produce a complete cut (Type 4 technique).
Copper	Copper up to 3% in steel permits of easy flame cutting.
Manganese	Manganese content up to 14%, with 1.3% carbon, allows for good cutting. However, high manganese steels require preheating before cutting to prevent cracking.
Molybdenum	Molybdenum content of 0.25%, as in chromium-molybdenum aircraft steels, does not hinder cutting. But a steel with 5.5% molybdenum, 8% tungsten, and 1% carbon is uncuttable, either hot or cold, unless special techniques are employed.
Nickel	Nickel in steel up to 7% does not hinder good flame cutting. Steels with 34% nickel have been cut where the carbon content was below 0.50%.
Phosphorus	Phosphorus content up to 2% does not prevent good gas cutting.
Silicon	Silicon in steel up to 2.80% permits of cutting by simple progressive method. Transformer iron, containing up to 4% silicon, can be gas cut, but high silicon content reduces speed. Precautions in preheating and cooling are necessary with certain of these steels in the upper ranges of carbon and manganese to prevent or modify air hardening tendencies.
Sulphur	Small amounts, such as are normally present in steels, have no effect. With higher percentages of sulphur, the rate of gas cutting is reduced and sulphur dioxide (SO_2) fumes are produced.
Tungsten	Tungsten up to 10% does not hinder flame cutting of steels, which contain also 5% chromium, 0.2% nickel and up to 0.8% carbon. A 17% tungsten content necessitates preheating before cutting and a procedure similar to cast iron cutting (Type 5 technique).

At times, flux cutting enables resistant materials to be cut by Type 1 flame cutting, which would otherwise require a more tedious technique.

Cutability of Ferrous Metals—Certain alloy steels contain chromium, nickel, and other elements in sufficient amounts to render them considerably more difficult to cut than carbon steels. The effect of various alloying elements on the cutability of steel, as reported by various authorities, is summarized in Table V.

Types of flame cutting techniques, as described in previous sections, which are employed with various ferrous metals are given in Table VI.

Table VI

¹The data apply to metal in the wrought, rolled, and cast condition unless otherwise noted. Preheating of any steel will, in general, improve the economy of cutting and prevent acute hardening. For carbon steels, heat treatment in one form or another is usually employed where the carbon content exceeds 0.30% provided the cutting is conducted at normal temperatures 60-80°F. If the temperature of the metal is lower than this, heat treating may have to be employed at a lower carbon content to preserve or re-establish desired physical properties. Where the letters CP or C-HT are given, it is meant that the material is cuttable cold, but requires either preheating

(Continued)

or reheating, as the case may be, to prevent damaging the cut surface or to preserve or restore commercial properties.

*The technique of cutting varies for different grades of steel. See the description of the five distinct types in the text.

*Heat treating practices employed for those grades which are unduly hardened by the normal application of flame cutting are listed in the table under the following classifications:

C—denotes that metal may be safely cut at room temperatures.

P—denotes that metal should be preheated before cutting to prevent hardening of the metal in the face of the cut. Usual preheating temperatures range from 500-900°F. Preheating is also used for certain grades to facilitate cutting.

HT—denotes heat treatment, furnace or otherwise, subsequent to cutting to improve or recondition the structure of the cut surface, provided the material is kept warm between the time of cutting and heat treatment.

*Unless otherwise indicated neutral preheating flames are to be assumed. However, appreciably higher preheating temperatures may be obtained by adjusting these flames for an excess of oxygen (oxidizing). Therefore, for cases where additional preheat is desired, oxidizing preheating flames may be used wherever neutral flames are indicated. Considerable economies are sometimes obtainable with oxidizing flames in which the ratio of oxygen to acetylene is about 1.7 or 1.8 to 1.

Car.—Denotes carburizing flame. A carburizing flame is one carrying an excess of fuel gas over that required for complete combustion.

*The addition of normal amounts of copper (up to 3.00%) does not interfere with the type of cutting nominally employed for the grade of steel in question. The addition of copper, however, does increase hardening of the cut surface necessitating introduction of heat treatment at a lower point in the aggregate of hardening alloys than would otherwise prevail.

*Grades SAE X-1314, X-1315 may harden perceptibly if carbon runs to the high side and is cut at normal or lower temperatures.

*Heat treating, after cutting, may be necessary if carbon runs to high side.

*There are no data available as to heat treatment for this grade, if necessary.

*Including SAE 4340 and 4315.

*Tungsten evidently may go to 10% with Type No. 1 cutting technique.

*All grades which respond to Type No. 1 cutting technique will readily respond to Type No. 2 technique either in conjunction with Type No. 1 technique or separately. The heat treatment for Type No. 2 corresponds to that respectively for Type No. 1.

*Heat treatment usually necessary to counteract harmful effects of the heating produced during the cutting operation unless the metal contains a stabilizing element to prevent such heat effects.

*Aluminum steel containing approximately 1% Al, 1% Cr and 0.50% Mo is reported to be cuttable by Type No. 1 technique. Heat treatment would depend upon the carbon content.

*The cut surfaces of the cast irons in heavy sections are hardened by the cutting operation and should be heat treated if they are to be machined after cutting.

*As the pressure of acetylene for the preheating flames is more a function of blowpipe or torch design than of the thickness of the part being cut, the pressure data, therefore, have been omitted from this table. For acetylene pressure data, see cutting apparatus manufacturers' charts.

†Lowest speeds and highest gas consumptions per linear foot are for inexperienced operators, short cuts, dirty or poor material. Highest speeds and lowest gas consumptions per linear foot are for experienced operators, long cuts, clean and good material.

‡Beyond 12 in. thickness, the critical data of manual cutting practices are greatly affected by the condition of the metal and the skill of the operator, resulting in wide ranges of data. In view of this, the table has been terminated at the 12 in. thickness.

The reader is referred to Table VIII, giving data on Machine Cutting wherein the thickness range has been extended to 20 in.

Hand Flame Cutting—Many variables affect free hand flame cutting performance. However, the range of fair average practice in free hand oxy-acetylene flame cutting of mild steel, not preheated, is given in Table VII. Oxygen and acetylene consumptions for cutting the various thicknesses up to and including 18 in. are listed, both in cu. ft. per hr. and cu. ft. per linear ft. of cut.

Free Hand "Guided" Flame Cutting—This includes such operations as circle cutting and drawing the torch head along a bar or straight edge which acts as a guide. Circles or discs can be cut accurately with a straight head hand torch, using a circle cutting attachment consisting of a clamp, radius rod and adjustable center point. Another attachment has small wheels which rest and roll on the surface of the work.

Flame Cutting Machines—Flame cutting machines are comparable with machine tools. They are capable of making flame cuts with jig-saw flexibility and of such high quality and accuracy the edges frequently require no further finishing.

Straight Line Machine Flame Cutting—Straight line machine flame cutting is even simpler than free hand flame cutting. Once the machine and gas pressures have been set the torch follows the line of cut automatically. As the cut progresses, the operator watches the drag and the flow of slag or oxide to prevent pocketing or other defects from developing. For oxy-acetylene machine flame cutting of mild steel, speeds and gas pressures should be adjusted within the ranges given in Table VIII.

*As the pressure of acetylene for the preheating flames is more a function of blowpipe or torch design than of the thickness of the part being cut, the pressure data, therefore, have been omitted from this table. For acetylene pressure data, see cutting apparatus manufacturers' charts.

†Lowest speeds and highest gas consumptions per linear foot are for inexperienced operators, short cuts, dirty or poor material. Highest speeds and lowest gas consumption per linear foot are for experienced operators, long cuts and clean and good material.

‡The apparent inconsistencies which will be noted in some of the columns in the table are due to the fact that there does not exist a straight line relationship between the elements of pressure, speed, and orifice sizes for the range of apparatus data from which this table was devised.

Shape Machine Flame Cutting—Regular or irregular shapes, of almost any size or thickness, no matter how complex, are machine flame cut with ease. The process has jig-saw flexibility. Shape cutting machines are mostly motor driven. Some have tracing devices which are manually guided around the outline of a drawing or templet of the required shape. One or more torches mounted on the machine duplicate the motion of the tracing device over the work, thereby flame cutting the shape traced. Other machines are fitted with motor driven guide rollers, which automatically follow a templet of the required shape, simultaneously controlling the movement of the torch so as to flame cut the same shape. Motor driven magnetized rollers, which adhere to steel templates as they advance automatically around the

contour, are a feature of certain machines. Some typical shapes, for which machine flame cutting is adapted, are illustrated in Fig. 9.

Circular Machine Flame Cutting—Most flame cutting machines can be adapted to circular cutting. With some, a radius rod with an adjustable center point is furnished. The point is placed in a center punch mark at the center of the circle and the machine and cutting torch travel around the circumference at the radius set. A short "lead in" cut through the scrap is customarily made, so as to have the finished cut smooth and unmarred at the starting point.

Precision Machine Flame Cutting—One machine flame cutting technique which produces especially high quality and accurate cuts is sometimes distinguished by the name "precision machine flame cutting." It will be noted in Fig. 3 that precision machine flame cutting has been set up as a separate division of machine flame cutting, to distinguish it from standard machine flame cutting, which is not so refined a process.

While the technique described under Type 1 cutting is, generally speaking, the one followed for precision machine flame cutting, closer adjustments of pressures and speed are required than for standard machine flame cutting. Cut surfaces true to within 0.003 in. as to cross sectional squareness for a 1 in. thickness have been attained by this method. For thicker material, cross cut tolerances increase approximately in proportion to the thickness. The cross cut tolerances for 1, 2, 4 and 6 in. thicknesses for precision machine flame cutting are shown in Fig. 10. These tolerances are not generally commercially available at this time.

Fig. 10—Cross cut tolerances, precision machine cutting practices.

Fig. 11—Flame drilling.

Machine Flame Cutting Table—The range of fair average practice in machine oxy-acetylene flame cutting of mild steel, not preheated, is given in Table VIII. Oxygen and acetylene consumptions for cutting various thicknesses up to and including 20 in. are listed, both in cu. ft. per hr. and cu. ft. per linear ft. of cut.

Flame Machining Operations—In flame machining, each operation is more or less a problem in itself, calling for a co-ordination of nozzle tooling and metallurgical control. Various types of flame machining operations have been included at the right-hand side of Fig. 3. It will be noted that these are termed planing, milling, turning, drilling, and boring, similar to corresponding machine tool operations. Subclassifications of these operations also are given in the chart. Not all of these operations have been commercialized up to the present time, however, some being still in the development stage.

Flame Planing—There are several types of tangential cuts which classify under the heading of "flame planing." The principal differences are primarily the character of application and the tolerances or degrees of surface regularity attained or permitted. Flame planing can be either manual or mechanical. The subclassifications are:

1. **Deseaming or Scarfing**—This process of flame planing is used in the steel mills for removing cracks or seams in billets, slabs, and rounds. It also is employed in steel foundries for exploring and cleaning out cracks and sand holes in castings.

2. **Hogging**—This application of flame planing performs the functions of removing superfluous metal in steel castings, either purposely provided or caused by defective conditions at the time of pouring, as well as those of removing risers and sprues whose location or character is such as to make it difficult or impossible to dispose of them by ordinary or Type 1 flame cutting.

3. **Surface Planing**—This operation is a step beyond the practices of "Deseaming," in that the cuts are caused to be adjacent to one another, thus enabling the removal of wide surfaces. When done mechanically, the dimension tolerances as to depth and width of cut can be kept to within $\frac{1}{16}$ - $\frac{1}{8}$ in. of the finished surface,

Flame Drilling and Punching—Fig. 11 shows a method used for flame drilling a round hole in the end of a billet for centering or piercing purposes. The dimensions of the finished hole can be made uniform and its walls straight sided, provided the nozzle or tip is properly held during the drilling operation.

The oxygen lance, described under Type 2 flame cutting, is also a valuable tool for flame drilling operations, particularly those of considerable depth, beyond the reach of cutting tips.

Rivet Cutting—Flame drilling has proven successful for rivet cutting by surface oxidation of heads. Cutting tips used for this operation have large cutting oxygen orifices of expanding, low pressure, low velocity type, together with high intensity preheating flames. The tip is held in line with the rivet, close to the head, so that preheating flames impinge on its center. As soon as a spot is heated bright red, the cutting oxygen is turned on slowly. This quickly oxidizes a crater in the head and consumes it. The shank of the rivet is then knocked out of the hole.

Flame Boring—Rough boring can be accomplished by means of a compound setting of the cutting flame. Application of this process depends largely on tooling to prevent the slag and molten metal from the cuts from interfering with the cutting and the operation of the cutting nozzle.

Underwater Cutting—There are two methods for torch cutting of submerged metals.

One method employs an oxy-hydrogen cutting torch fitted with a bell or skirt around the tip, which is filled with compressed air to supply additional or atmospheric oxygen for combustion of the hydrogen, and also to hold the water away from the preheating flames and the cutting area.

The other method consists in using oxy-acetylene torches for underwater cutting at shallow depths (less than 35 ft.). At greater depths the fuel gas pressure required to overcome the hydraulic head is beyond the safe operating pressure of acetylene, and hydrogen is used. When using acetylene, considerably more compressed air must be supplied.

Only divers who have been specially trained in underwater cutting can practice it successfully. The tips are liable, for some obscure reason, to side perforations while operating. Quite a little underwater cutting has been done with hydrogen at depths of 135 ft. or more on sunken submarines, bridge caissons, submerged wrecks, and steel piling.

Safety Rules—Certain precautions must be observed for the safe handling and operation of gas cutting tools and appurtenant equipment. Standard Rules and Regulations have been promulgated by the cutting industry in co-operation with regulatory bodies dealing with the public and workers' safety. In "Safe Practices Bulletin No. 23," published by the National Safety Council, and in "Regulations for the Installation and Operation of Gas Systems for Welding and Cutting," issued by the National Board of Fire Underwriters, the subject of general safety as it applies to gas welding and cutting processes is well covered.

Electric Arc Cutting—The process of electric arc cutting is purely one of applying the heat energy of the electric arc to melt the metal along the desired line of cut. Due to the extremely high temperature developed in the electric arc, it can be used to fuse almost any electrical conducting material and, in this way, is employed for cutting metals. Arc cutting is, of course, not a true cutting process, since the metal is merely melted away. It does not equal gas cutting from the standpoint of smoothness, quality, or accuracy of cut surfaces, and hence, is not used where high quality, accurate cuts are required. It is, however, useful where smooth, uniform cut surfaces are not essential and merely severing is the main object, as in scrapping operations. Arc cutting is also used for metals not easily cut in any other manner, such as cast iron, manganese steel, and large sections of non-ferrous metals. It is particularly applied to cutting risers of large manganese steel castings. Rivet cutting and hole piercing are other operations for which arc cutting is used.

Carbon Arc Cutting—This process consists essentially of drawing an arc between a carbon or graphite electrode and the material to be cut. Direct current is generally used, with the carbon electrode negative (straight polarity), although alternating current can be used also. Graphite electrodes are preferred to carbon electrodes, as they have a much longer service life and retain a point longer. The latter is essential for clean, smooth cuts. The heavy currents used for arc cutting make ordinary electrode holders unsuitable, except for light work. Special holders

with long shank, special gripping mechanism, and hand protecting shield are recommended.

Manipulation of cutting arc, when cutting plates of $\frac{1}{4}$ in. thickness or less, consists simply in advancing along the line of cut at a rate equal to that at which the metal is being melted away. The most smooth and uniform cuts are obtained with the plate in the horizontal plane, but the operation may be done with the plate in inclined or vertical position also. In horizontal cutting, the electrode is held vertical or pointed slightly forward. For inclined or vertical cutting, the electrode is pointed downward. When cutting materials heavier than $\frac{1}{4}$ in., the vertical face of the cut is progressively melted away by working from top to bottom, thereby having the bottom of the cut advanced slightly ahead of the top of the cut and producing an undercut which permits the molten metal to run out more easily. Skilled operators can make narrower cuts. The width and speed of the cut increase with the current and the electrode diameter. Recommended current values for different size graphite electrodes are given in Table IX.

Table IX
Current Values for Arc Cutting

Electrode Dia., in.	Current Values in Amperes
$\frac{1}{4}$	Up to 200
$\frac{3}{8}$	200-400
$\frac{1}{2}$	300-600
$\frac{5}{8}$	400-700
$\frac{3}{4}$	600-800
$\frac{7}{8}$	700-1000
1	800-1200

Rivet Cutting by Carbon Arc Process—The best results are obtained with the plates in the vertical position. If the plates are in the horizontal position, and rivets are being cut from the top of the plate, the molten metal is removed by an air blast or by mechanical means. If rivet heads are cut underneath the plate, the molten metal is removed by gravity, as when removing rivets from vertical plates. Where plates are to be salvaged the arc should not be struck on them as it is apt to burn a depression. Rather the arc should be struck on the rivet head and rotated slightly, care being taken not to concentrate it too long at the periphery of the rivet head. For rivet cutting, a $\frac{1}{4}$ - $\frac{5}{8}$ in. graphite electrode using 400-600 amperes current is recommended.

Arc Cutting with Coated Electrodes—The application of heavily coated electrodes to cutting is not always an economical process, but has certain merits, particularly where no oxy-acetylene cutting torch or graphite electrode is available. Electrodes with either gaseous or slagging type coatings can be used, but the latter give better results because they will handle higher current densities. Plates up to $\frac{1}{4}$ in. thick can be cut by simply advancing the electrode along the line of cut. On heavier plates the electrode is pointed forward and moved from the top to the bottom of the cut, so as to keep the bottom slightly ahead. Electrodes smaller than $\frac{3}{8}$ in. dia. are not suitable for arc cutting. The width of the cut is approximately constant for all electrodes up to $\frac{1}{4}$ in. dia. Alloy steels and many nonferrous metals can be readily cut by the coated electrode cutting process.

Piercing Holes with Coated Electrodes—Coated electrodes can also be used to pierce holes in plates. This process is applied in cases where a hole is desired and it is impractical to punch or drill it, or use gas cutting. The operation depends on the formation of a crater at the end of the electrode which results from the steel core melting faster than the surrounding coating. This permits pushing the electrode end against the plate without shorting the circuit. Consequently, there is still a gap between the metal conductors and the electric arc does not become extinguished. High current is applied to the electrode. The arc is struck at the point where the hole is to be pierced and the electrode given a circular motion, equal to the diameter of the hole to be pierced, until the surface of the metal is melted. Then the electrode is pushed down against the molten metal and the circular motion continued. This will cause a hole to be melted through the plate.

Principles of Heat Treatment of Iron and Steel*

By E. S. Davenport*

Introduction—The purpose of this article is to outline the principles underlying the heat treatment of ferrous materials. These fundamental principles are used when one intentionally alters the mechanical properties of steel by heat treatment in order to make it more serviceable for some particular purpose. The general aim of heat treatment is to *improve* some property or combination of properties as compared to the condition of the material prior to the heat treatment; for example, if the properties in the hot rolled, cold rolled, or cast condition are not suitable for some particular purpose a heat treatment is applied to develop the desired structure and properties. A misunderstanding of the principles involved may result in a heat treatment which develops *inferior* properties instead of the intended improvement. It is necessary, therefore, that anyone attempting to devise a treatment for a new material or for the development of new combinations of properties, should have a thorough grasp of the fundamentals of the subject.

An article on the subject of heat treatment of metals in general appears on page 198. The present article confines itself to the heat treatment of steel and, moreover, is limited to a discussion of principles. For more specific information on the heat treatment of particular classes of steels, reference may be made to other articles in this volume.

General Principles—The following definition of heat treatment has been adopted by the S.A.E., A.S.T.M., and the A.S.M.

Heat Treatment—An operation or combination of operations, involving the heating and cooling of a metal or an alloy in the solid state for the purpose of obtaining certain desirable conditions or properties.

Note—Heating and cooling for the sole purpose of mechanical working are excluded from the meaning of this definition.

In spite of this "Note" it should be borne in mind that the cooling from hot working operations, such as rolling or forging, may, and often does, constitute a heat treatment just as much as if a separate heating and cooling cycle were applied. For many purposes, of course, the structure and properties resulting from such cooling may not be those desired, in which case further heat treatment is necessary.

It is assumed that the reader has a good working knowledge of the iron carbon diagram and the allotropy of the element iron, and recognizes the fact that the whole art and science of the heat treatment of steel is based upon the fact that there are two forms of iron: Alpha (ferrite) and gamma (austenite). It is the difference in solvent power of these two forms of iron for carbon and other alloying elements which places at our disposal the wide range of properties capable of being developed by heat treatment in ferrous materials.

In general, all heat treating processes involve two fundamental operations: A heating cycle, and a cooling cycle. A third factor—the element of *time* at one or more temperatures either in the heating, cooling or tempering cycle—must be taken into consideration in devising a heat treatment schedule for any particular steel. Some of the questions which must be answered in developing such a schedule are: How hot and at what rate should the steel be heated? How long should it be held at temperature? At what rate should it be cooled? Is the heat treatment to be considered as finished at the end of the cooling cycle or is a tempering treatment required? If tempering is necessary, what heating, cooling, and time-temperature cycles are to be followed? Let us now consider these questions in somewhat greater detail and attempt to arrive at answers from the viewpoint of general principles. It is realized that, in practice, the size and shape of the part being treated must be taken into account; but except where otherwise noted, this factor will be neglected in the following discussion as it does not affect the principles involved. Articles dealing more fully with this aspect of heat treatment appear elsewhere in this volume (Relation of Design to Heat Treatment, page 214, Mass Influence in Heat Treatment, page 512).

Heating—The first step in the heat treatment of steel is the heating of the material to some temperature either in or above the transformation range in order

*Metallurgist, United States Steel Corp., Research Laboratory, Kearny, N. J. Prepared for the Subcommittee on the Heat Treatment of Metals. The membership of the subcommittee was as follows: R. S. Archer, Chairman; J. F. Gill, W. G. Hildorf, G. C. Lilly, W. B. Price, C. T. Willard, and E. S. Davenport.

to put the iron in the gamma condition; the carbon and other elements are thus caused to dissolve in the gamma iron and to form the homogeneous solid solution, austenite. The solution of these elements may be either partial or complete, depending upon the time-temperature cycle. This austenite solid solution is the raw material out of which we build the final structure of ferrite and carbide in the subsequent cooling, or cooling and tempering operations.

Heating Rate—For many purposes the rate of heating is not as important as certain other essential features of the heat treating cycle such as, for example, maximum temperature, time at temperature, and rate of cooling. The initial condition of the material, with respect to internal stress produced by cold work or otherwise, may have an important bearing on the optimum heating rate because of its influence on distortion and cracking, and on the initial size and growth characteristics of the austenite grains; moreover, the volume change accompanying the alpha to gamma transformation as the metal passes through the transformation range must be taken into consideration in selecting a heating rate. Hard, brittle, highly stressed materials, such as steels in the martensitic or fully hardened condition, should be heated more slowly and carefully than is necessary for stress-free materials; otherwise cracking may occur. On the other hand, materials which have been subjected to a certain amount of cold working may exhibit a tendency to germinative or excessive grain growth when heated slowly through the transformation or recrystallization range; in such cases a rather rapid rate of heating through the germinative temperature range is indicated if excessive grain growth is to be avoided.

The thermal conductivity of the material, the nature of the furnace atmosphere (whether scaling or nonscaling) and the thickness of section, all have an influence on the behavior of the steel in relation to the rate of heating. The difference in temperature rise within thick and thin sections of articles of variable cross section is, of course, an ever present problem in practical heat treating operations; whenever possible, provision should be made for retarding the heating of the thinner sections in order to minimize thermal stress and distortion. In general, the heating rate should be such as to avoid injury to the material through excessive thermal and transformational stresses, but the possibility of germinative grain growth should be kept in mind. Indeed, uniformity of proper temperature throughout the material is the ultimate objective of the heating cycle; in most instances this uniformity will be attained more safely, and with less over-all damage to the steel, by slow heating than by fast heating.

Maximum Temperature—The selection of the maximum temperature will be determined to some extent by the chemical composition of the steel, the proportion of carbide or ferrite it is desired to put into solution in the austenite, and the maximum permissible austenite grain size if the latter has been defined or specified. In general, the higher the temperature, within limits, the greater the solubility of the phases (carbide or ferrite) and the greater the rate at which they are dissolved in the austenite; likewise, the higher the temperature, other things being equal, the larger the austenitic grain size.

For plain carbon, hypoeutectoid steels (below about 0.85% carbon) a temperature just above the upper transformation or critical temperature (A_3) is usually recommended. At this temperature (A_3), which, of course, varies with the carbon content of the steel, the transformation from alpha to gamma on heating is just completed, that is, all of the carbide and proeutectoid ferrite is in solid solution; thus maximum solubility of the constituents is achieved with minimum growth of the austenite grains. As the temperature is raised above the A_3 for any given steel, the austenite grains begin to grow; such grain coarsening is sometimes desirable for improving machinability; less frequently it is employed to increase hardenability (depth of hardening) although deeper hardening can usually be achieved better by other means.

For plain carbon, hypereutectoid steels (above about 0.85% carbon) a temperature between the lower transformation or critical temperature (A_1) and the upper critical (A_{cm}) is usually recommended. The upper critical line (A_{cm}) in the iron-carbon diagram rises so steeply with increasing carbon content above 0.85% that an excessively high temperature may be required to dissolve all the proeutectoid carbide in the austenite; this tends to develop undesirably coarse austenite grain size with consequent deep hardening and cracking effects. If it is desired to take full advantage of the hardening effect of the carbon and of the alloy content, it may be necessary to have most of the carbide in solution, in which case a tempera-

ture just at, or slightly above, the A_{cm} temperature must be employed; otherwise, it may be preferable to leave some of the carbides undissolved in order to restrain austenite grain growth and to act as transformation nuclei on cooling; when this is done a part of the potential hardenability of the steel is sacrificed in order to limit or control grain growth and depth of hardening. Undissolved carbides are almost always present to some extent in the austenite of alloy steels containing the reluctantly-soluble carbides of elements such as chromium, vanadium, molybdenum, and tungsten; excessively high temperature or an absurdly long heating period would be required to put all of these carbides into solution.

To summarize then, the maximum temperature in the austenitic range should be just high enough to achieve the necessary extent of solution of the constituents, ferrite or carbide, but no higher. The austenite must be held long enough at temperature to become essentially homogeneous and rich enough in carbon, and in such alloying elements as may be present to bring about the desired hardening in the subsequent cooling operation; yet excessive growth of the austenite grains should be avoided, in so far as possible. If for any reason, a coarse austenitic grain size is desired, a higher maximum temperature should be used.

Time at Maximum Temperature—In general, time at temperature has an influence similar to maximum temperature, as discussed in the preceding section. In any heat treating process *temperature* and *time* must be considered simultaneously since practically all changes in metals take place more rapidly at higher temperatures, owing to the increased atomic mobility. Thus the longer the time at any given temperature in the austenitic range, the greater will be the amount of carbide and alloying elements (if present) taken into solution, the more homogeneous the austenite due to diffusion of these dissolving elements and the larger the austenitic grain size—all within limits fixed by the equilibrium conditions of these reactions at the particular temperature under consideration. Carbide particles, in particular, require a surprisingly long time interval for complete solution even when the temperature is such as to cause their ultimate solution, that is, above A_{cm} .

Since the constitutional changes which we aim to bring about at the maximum temperature are comparatively rapid, the element of time is less important than the actual temperature itself. In general, a relatively small increase in temperature will have a far greater effect in accomplishing the desired change than a longer time at some lower temperature; this is particularly true for the diffusion and grain growth changes mentioned above. On the other hand, when we consider the question of time at temperature from the standpoint of thickness of section, thermal conductivity of the metal, scaling, decarburization and other surface reactions dependent upon furnace atmosphere, the time factor assumes greater significance. The heavier the section or the lower its thermal conductivity, the longer the time necessary to attain uniform temperature throughout the piece; in the great majority of cases, uniformity of temperature throughout the piece is highly essential. Scaling, decarburization and similar surface phenomena all proceed continuously with time at temperature and if these effects prove to be detrimental it behooves the heat treater to keep the time as short as possible. Many of these surface reactions can be limited or even advantageously utilized by proper adjustment of the furnace atmosphere as, for example, when we intentionally introduce elements into steel by means of carburizing, nitriding, or a similar treatment.

In general, the time at maximum temperature should be long enough to attain uniformity of temperature and to bring about the desired constitutional changes; it frequently happens that these two aims can be accomplished in about the same time. On the other hand, the time at temperature should be kept to the minimum consistent with the above requirements in order to avoid undesirable effects from austenitic grain growth or surface changes due to the heating atmosphere.

Cooling—When the steel has attained the predetermined temperature throughout, the next step is to cool it at the proper rate to develop the desired structure. When, for a given steel, the austenite on cooling transforms to an aggregate of ferrite and carbide, or to martensite, the resultant structure—hence the mechanical properties—is, to a large extent, determined by the temperature at which this transformation actually takes place. With a slow cooling rate only moderate undercooling occurs; the transformation takes place just slightly below the lower critical temperature (A_1), and the resulting structure is characterized by coarse, lamellar pearlite of relatively low strength and hardness and high ductility. With such a slow cooling, there is, in addition to the pearlite reaction, a precipitation of proeutec-

toid ferrite in hypoeutectoid steels and of proeutectoid carbide in hypereutectoid steels; these proeutectoid constituents usually precipitate in the austenite grain boundaries and thus outline the austenite grains which existed at the maximum temperature; advantage is taken of this behavior in making austenite grain size measurements in hypo and hypereutectoid steels.

With progressively greater rates of cooling the actual temperature of transformation is progressively lowered by undercooling until, eventually, it is depressed to temperatures in the vicinity of 950-1000°F.; the lamellar pearlite becomes progressively finer, stronger, harder and less ductile, and the precipitation of the proeutectoid phases—ferrite or carbide, as the case may be—gradually diminishes in volume until finally at the faster cooling rates, it may be suppressed altogether. However, in the very low-carbon steels (0.20% carbon and lower) there is so much excess ferrite available that its precipitation ordinarily cannot be suppressed even with the most drastic cooling.

If the cooling speed is increased still further, as in quenching, the transformation is depressed by undercooling to temperatures approaching room temperature; the product of the austenite transformation at these low temperatures is not pearlite, but martensite, the characteristic constituent of fully hardened steel. The cooling rate which just causes the steel to harden fully to the martensitic condition is known as the "critical cooling speed"; it depends upon the composition and the austenite grain size of the steel. Martensite is now generally considered to be an unstable, supersaturated solid solution of carbon in alpha iron; it is glass-hard, brittle, and in steels carrying more than about 0.5% carbon, always in a condition of high internal stress, due, in part, to the volume changes accompanying the gamma to alpha transformation, to the solid solution effect, and to the drastic cooling which the material underwent in the hardening operation. In this condition steel is ready to precipitate its carbon and to relieve itself of stresses at the first opportunity, as, for example, on reheating for tempering or drawing-back. In some cases, fully hardened steel may relieve itself of internal stresses by spontaneous cracking, a fact well known to practical heat treaters.

At cooling rates intermediate between those giving rise to the pearlitic structures and those yielding martensite, mixtures of the two structures may be formed due to part of the transformation occurring at the higher temperatures and part at the lower; this mixed structure is always encountered in the transition zone between the hardened exterior and unhardened core of quenched heavy sections in which the surface may have cooled fast enough to form martensite while the interior cooled more slowly and transformed to the softer pearlitic products at higher temperature. Thus it is evident that thickness of section has a marked influence on the depth to which a given steel may be hardened (hardenability) at any particular cooling rate.

Effect of Alloys—The mechanism by which, at any particular cooling rate, dissolved alloy content depresses the transformation to lower temperatures as compared to carbon steel, is now fairly well understood. The action is due to the retarding of the fundamental transformation rate of the alloy bearing austenite, causing the finer, harder pearlitic structures to be formed at any given slow cooling rate or resulting in deeper hardening characteristics on rapid cooling—all, of course, as compared to plain carbon steels. Thus it corresponds to a faster cooling rate prior to the beginning of transformation as compared to carbon steel. A so-called "air hardening" steel, therefore, is one in which the transformation rate has been so retarded by the addition of alloys as to form fully hard martensite even on moderately slow cooling from the austenitic condition. In high alloy steels containing substantial amounts of the austenite-stabilizing elements the austenite solid solution may be retained all the way down to room temperature by the use of even very moderate cooling rates such as air cooling; these steels constitute extreme examples of the retarding of the fundamental transformation rate by the addition of alloying elements.

Effect of Austenite Grain Size—Increasing the austenite grain size by employing higher maximum temperatures before cooling has an effect upon hardenability similar to that of adding alloys; coarsening the austenite grain retards the fundamental transformation rate and results in harder, finer pearlitic structures, or deeper hardening characteristics, for any given rate of cooling as compared to the same steel in the fine grained condition.

Effect of Thickness of Section—The influence of size of section must be taken into account in any consideration of the subject of heat treatment from the stand-

point of cooling rate. A heavy section cannot be cooled as rapidly as a thin section; the interior of a heavy section cooling more slowly than the surface, transforms not only at a later time, but at a higher temperature and hence to a softer product than the more rapidly cooling exterior. This gives rise to differences in properties between the interior and exterior as well as to possible distortion, nonuniform internal stress and other difficulties well known to those familiar with heat treating practice; the subject is discussed more fully elsewhere in this volume, page 512.

Effect of Condition of Surface—Another factor which may be mentioned in connection with cooling practices is that of the surface condition of the metal about to be cooled. Steel which carries a heavy insulating coating of scale from the heating operation cannot be cooled as rapidly, under a given set of cooling conditions, as steel which is free from scale. This may result in erratic and non-uniform properties in the final product, particularly in connection with treatments designed to achieve full hardening; soft spots, or in extreme cases, complete lack of hardening may result from attempts to quench badly scaled steel. The remedy, of course, is either to descale in some manner before cooling, or practically, to carry out the heating operation in a less severely scaling atmosphere. Decarburization may cause nonuniform hardening and other undesirable effects, particularly as reflected in the behavior of the material under repeated or alternating stress (fatigue).

To summarize the effect of cooling rate on a given steel, the slower rate yields the softer pearlitic structures while the rapid rate gives rise to the harder, martensitic structures; the former are relatively stable and stress-free while the latter are quite unstable and are likely to be so highly stressed internally as to be unserviceable for most purposes. This brings us to the question of whether the heat treatment is to be considered as completed at the end of the cooling operation or whether a further treatment is necessary. Ordinarily, the softer, pearlitic products resulting from the slow cooling operations require no further treatment since they are relatively stable (although not entirely so) from a structural standpoint. Occasionally, the fine, pearlitic structures are given a low temperature (subcritical) stress relieving anneal; such a treatment tends to spheroidize the fine lamellar carbides, the extent of spheroidization depending upon the temperature and time of the annealing operation. On the other hand, the harder, martensitic products, resulting from rapid cooling or quenching, are usually so unstable and brittle as to be of little practical value in the "as quenched" condition; hence a further treatment known as *tempering* is almost invariably applied.

Tempering—Tempering of fully hardened steel is carried out for relief of quenching stresses and for the recovery of a limited degree of toughness and ductility. The operation consists of heating at temperatures below the lower transformation or critical temperature (A_1), that is, at temperatures at which the steel is in the ferritic condition. The stress relief and recovery of ductility are brought about through precipitation of carbide from the supersaturated, unstable alpha iron solid solution (martensite) and through diffusion and coalescence of the carbide as the tempering operation proceeds.

It should be clearly understood that the carbide precipitation which occurs during the tempering of martensite does not take the form of plates or lamellae characteristic of the pearlitic structures formed directly out of austenite on slow cooling; on the contrary, the carbide precipitated during tempering takes the form of a fine dispersion of more or less spheroidal particles, the size of which depends upon the time-temperature conditions of the tempering operation; this cannot be emphasized too strongly since there appears to be considerable confusion on this particular point. So far as is known, no one has ever succeeded in making lamellar pearlite out of martensite by a subcritical tempering treatment. The tensile properties of a tempered specimen (spheroidal carbides) and a pearlitic specimen (lamellar carbides) of the same steel, at the same hardness, are distinctly different.

The higher the tempering temperature, or the longer the time at temperature, the coarser the spheroidal carbide particles and the softer and more ductile the steel. Alloy steels containing the carbide forming elements tend to show greater resistance to softening in tempering than plain carbon steels; hence higher temperatures or longer times may be employed in tempering such steels, thereby attaining more thorough relief of quenching stresses without proportionate sacrifice in hardness.

Some steels are susceptible to embrittlement, or at least a reduction in ductility,

when tempered in the so-called "blue heat" range, or when slowly cooled through this range after tempering. This, which is due presumably to some precipitation in the steel, can be minimized either by tempering at temperatures below the range in which the steel is sensitive, or by rapid cooling through the range if the tempering temperature is above it.

In general then, the tempering operation may be conducted so as to give almost any desired combination of properties by proper selection of the time-temperature conditions. The correct time-temperature cycle for any given set of properties depends, to a large extent, upon the composition of the steel, and particularly the composition of the austenite with respect to its dissolved carbon and alloy content prior to its conversion to martensite by rapid cooling.

Flame Hardening*

General—The "flame hardening" process, also known as the "Shorter" process or "Shorterizing," embraces the use of the oxy-acetylene flame to raise the temperature of the surface of ferrous material above the Ac₁ transformation point so that subsequent quenching will produce a desired hardness and structure.

The hardened layer varies in depth from a mere skin to $\frac{1}{4}$ in., according to the operating practice and type of material being treated. This method forms a hardened case on the surface of the parts being treated without altering the chemical composition, so must not be confused with such processes as carburizing, cyaniding, or nitriding that require the addition or absorption of other elements.

Comparison of Furnace and Flame Hardening—For mass heat treating of small objects which are to be uniformly hardened the furnace method is usually the most efficient and economical. There are many instances where the parts are too large or where there is danger of excessive distortion when using the furnace method. In such cases, the oxy-acetylene flame may be used to advantage since this process permits the hardening of any accessible portion of an article with negligible distortion.

Distortion—While flame hardening tends to minimize distortion, there are applications which must be held to little or practically no distortion. The amount of warp is not predictable and frequently it is not possible to prophesy the direction of distortion. The composition of the material, its physical condition, the depth and degree of hardness, and the section undergoing treatment should be considered. Practically, the answer must be determined by experiment on the particular section. Distortion is greatest when only one side of a thin object is heated and quenched. Often it will be found that some simple expedient such as a water bath or compensative heating on the opposite side from which the flame hardening is being done will hold distortion to a minimum. In sections where both sides of an object are hardened simultaneously, such as gear teeth, distortion is practically nil. Where the metal section between the bore and root diameter is less than $1\frac{1}{2}$ in., the bore may expand several thousandths.

Materials—Steels—To obtain any appreciable degree of hardening, the material treated must be of such a chemical composition as to readily respond to heating and quenching. For carbon steels the carbon content should be at least 0.35%; the best range is 0.40-0.70%. Steels with a higher carbon content may be successfully flame hardened, but greater care has to be exercised to prevent surface checking or cracking.

The high alloy steels produce a more difficult problem in heating and quenching, and many are to be avoided. Table I illustrates the type of steels that have been successfully flame hardened.

Cast Iron—Pearlitic cast irons and malleable irons offer a broad field for the flame hardening process. Chilled, cast iron has a high resistance to wear, but ordinary chilled castings can not be used when machined surfaces are required and where dimensional accuracy is important. It is here that flame hardening is particularly useful, because the wearing properties of cast iron surfaces are greatly increased by this process. Table II shows the results obtained in flame hardening a number of cast irons.

Properties—This method of heat treatment produces the optimum hardness on the surfaces subjected to wear, but leaves the core in its original condition. This makes it possible to heat treat the core to the desired properties and then impart a hard surface layer without altering the core.

Hardness—The surface hardness that can be anticipated from flame hardening any of the steels tabulated in Table I at least equals the same as would be obtained from these analysis if hardened in a conventional heat treating furnace and quenched. Table III gives hardness values for a guide as to what may be obtained.

The hardness is maintained through about 80% of the depth of the hardened area. The core is not affected and there is no rapid falling off of the hardness, the transition from case to core being gradual (Fig. 1). As a sharp line of demarcation between the case and core is not observed flaking and spalling under service stresses are avoided.

Application and Methods—This process may be adapted to castings, forgings, or rolled sections. Size is not a limiting factor and if the part is fabricated from material of the proper analysis and the sections which require hardening are readily accessible, then the part may be flame hardened.

Flat sections, circular parts, irregular shapes and varied combinations may be successfully hardened by this method.

The Stationary or Spot Hardening Method—This method includes operations where the torch and work are stationary during the treatment.

Fig. 1—Hardness exploration of flame hardened case on S.A.E. 1045 steel.

Straight Line Progressive Method—In this method, the torch and quench travel along the face of the object such as gear teeth or track rails. With this procedure only the material directly under the heating head is undergoing treatment at any instant.

Rotary Progressive—In this method, cylindrical objects of large diameter are rotated at a speed of from 3-12 in. per min. in front of a stationary flame. The torch being mounted so that it progressively heats and quenches the desired width of path to be hardened. This method leaves at the starting and stopping points a

*These steels are recommended to be hardened by the spinning method only.

narrow oblique path which is generally two or three points softer on the Rockwell than the adjacent hardened areas. The tempering of the hardness at the overlap may be held to a minimum by placing an auxiliary cooling stream ahead of the torch.

Large cylindrical pieces may be hardened by mounting the torch in the tool post of a lathe and moving the carriage slowly along the cylinder axis, producing a spiral path, the width of the strip depending on the width of the torch. Where complete hardening is desired the paths should overlap about $\frac{1}{4}$ in.

Spinning Method—For hardening gears under 4 diametrical pitch and producing hardened bands on cylindrical surfaces of small diameter, the spinning method is employed using a water cooled tip without quenching jets. The heating flames cover the entire width of the path being hardened while the object is rotated rapidly (at a surface speed of approximately 100 r.p.m.). When the surface of the object has been heated to the desired temperature, the flames are extinguished, and the part is ejected or dropped into a tank of quenching medium or a spray quench is directed upon it. Where larger diameter surfaces are to be hardened it may be necessary to use two or more heating tips spaced equally around the cylinder circumference.

Progressive Spinning—This method may be employed for the hardening of cylindrical surfaces of extended length by progressing a heated band followed by a quenching stream along the axis of the cylinder being heated at the general progressive hardening speed of 3-12 in. per min. The work is mounted on centers and rotated at a speed of about 100 r.p.m. One or more torches, depending upon the diameter of the object, are mounted with the quenching arrangement on a separate carriage and are spaced at equal intervals along the objects perimeter so as to heat a narrow band. Moving the carriage slowly, the heated band is progressed along the axis of the cylinder followed by the quenching stream.

Hardening Irregular Surfaces—Irregular contours may be hardened by using specially designed torches. In many instances it is preferable to divide an irregular shape into several sections and treat each part as a separate operation. This method permits simplification of torch design as well as promoting easy operation, but it has the disadvantage that in certain applications or design, there may be produced zones of lower hardness at the junctions of the different sections.

Equipment—While there are instances where torch hardening must be performed by hand, most all operations may be mechanized and in order to reduce cost and obtain consistently uniform results, mechanical means should be used.

There are several types of flame hardening machines used in the United States, the Monitor, Radiograph, Sykes machine, the Gleason design, the Universal type, camshaft and rail hardening machines. Variable speeds of travel on all types of machines permit uniform treating of sections of different sizes and varying cross sections.

Torches—The recent developments of dependable internally water cooled torches and multiflame tips, capable of maintaining stable flames under severe heating conditions, in close proximity to the heated surface, and the operation of these tips by mechanical means have made possible the application of the flame hardening process to industrial production.

Tips—A large selection of flame hardening tips for hardening gear teeth, flat, round, and cylindrical surfaces; both internal and external are available. In general, for progressive hardening, the tips have integral water quenching jets at the proper distance to the rear of the heating flames, which progressively quench the surface as it is heated. The water jets perform two functions, that of cooling the tip, as well as quenching the heated surface. For other applications where the surface is first heated and then quenched separately, the tips are designed with internal cooling while an auxiliary quenching stream is used for quenching after the heating flames have been extinguished. These quenching streams may be built into the tip or may be separate.

Gear Hardening—In gear hardening the head is designed to allow operation in the restricted area between the teeth. Although it has been the practice until quite recently to flame harden the opposite sides of each tooth separately, the development of the "straddle type" heads has made simultaneous treatment possible.

With this method the gear may be hardened in half the time formerly required. In addition to time saving, the simultaneous application by the straddle method leaves both sides of the tooth hardened uniformly. As the straddle method provides for heat and quench striking both sides of the tooth simultaneously, the tendency for small teeth to distort is overcome.

To insure equal hardness and contour on each side of the tooth, the distance from tooth faces to head faces must be equal, and the flame intensities and gas

Section of flame hardened gear tooth showing case.

ratios the same. The leading flames of the heads must arrive at the entering end of the tooth at the same time.

Quenching pressures are important, especially on the small tooth sizes. Too much pressure will interfere with the flames, and too little pressure may not produce sufficient hardness.

Stress Relieving—Tempering or stress relieving is absolutely essential and should follow shortly after quenching. This operation is performed in a standard type heat treating furnace or air or oil bath at temperatures from 350-400°F. This low temperature is sufficient to relieve the stresses set up by quenching, but has little if any effect on the hardness. After this tempering operation the work may be removed from the furnace and cooled in still air or may be furnace cooled.

Economics—Computation of cost and gas consumption per unit area depends upon several varying factors, such as set up time, case depth, method used, rate of torch travel, size of tip, and relation of the surface to mass of the object treated. It would appear that owing to these variables only an approximation can be made. A fair estimating figure is that $\frac{1}{4}$ cu. ft. of each gas will flame harden one sq. in. of surface to a depth of about $\frac{1}{8}$ in. In certain practices this figure has been reduced to $\frac{1}{8}$ cu. ft. of each gas per sq. in. of surface treated; speed range 3-10 in. per minute.

Precautions—While this method of hardening appears simple, there exist a number of variables which have to be carefully regulated and co-ordinated to insure the most satisfactory results.

Since flame hardening is only surface hardening and only a comparatively thin layer is treated, it is of the utmost importance that this surface be in the proper condition to successfully respond to this operation. Decarburized zones are to be avoided. The components must have the requisite carbon content at the surface as well as underneath.

The surfaces to be hardened must be scale-free as scale retards the quench and maximum hardness will not be attained. Pits, blow holes, seams and laps, are to be avoided as they may result in the formation of large surface holes or develop into cracks during the quenching operation.

This method produces no scaling or pitting and the hardened surfaces are left clean and smooth but precaution must be taken, because a temperature of 6300°F. is applied at a distance of only $\frac{1}{4}$ in. from the surface desired to heat to a temperature range of only 1450-1550°F. Positioning the flame too close to the work, or applying it for too long a time, may result in searing or burning the surface material and producing a brittle and coarse underlying grain, or it may result in overhardening and surface checking.

The operator must learn to judge the proper quenching temperatures and while this varies with different steels, practice will soon permit him to judge with fair accuracy. The light of the flame makes the steel appear colder than the actual temperature and a new operator may overheat the work. Inexperienced operators often report that the material is excessively hot under the last two flames but cold in between, but with a properly designed head the heat will be distributed satisfactorily although the appearance under the flame would tend to indicate otherwise.

Heat Treatment of Carbon Steels*

General—This article covers the heat treatments for carbon steels of all commonly used types except those classified as tool steels. All common applications are covered except those of case hardening, spring making and the hardening of tools. From the treatments not covered, see appropriate sections of this Handbook.

Chemical Composition—The composition of the steels covered are the S.A.E. specifications for carbon steels as given on page 612.

Heat Treatment—General—Table I gives the commonly used temperatures and quenching media for heat treating some of the carbon steels. The S.A.E. carbon steels whose treatments are representative of a particular carbon range are the only steels listed in Table I. For a discussion of the principles involved, the reader is referred to the articles "Heat Treatment of Metals" and "Principles of the Heat Treatment of Iron and Steel" given in this Handbook.

Table I
Heat Treatments for Carbon Steels

S.A.E. No.	Normalize, °F.	Anneal, °F.	Quench, °F.	Quenching Medium

1080	1500-1575	1475-1550 or 1250-1400 ²	1400-1525	Water ³ -Oil
1095	1500-1575	1475-1550 or 1250-1400 ²	1400-1525	Water ³ -Oil

¹For explanation of double temperature range, see discussion of Group I. ²This temperature range is for spheroidizing. ³Brine or caustic soda solution is frequently used. ⁴Soluble oil solution is used for hardening bolts. ⁵Mineral oil is used when treating for machinability only.

To simplify further discussion of the treatment, the steels will be classified as follows: Group I, S.A.E. 1010-1025; Group II, S.A.E. 1030-1050; Group III, S.A.E. 1055-1095.

Group I, S.A.E. Steels 1010-1025—There are three important kinds of heat treatment used on these low carbon steels: (1) Process treating of material to prepare it for subsequent operations; (2) treatment of finished parts to improve physical properties, and (3) case hardening, which is covered elsewhere in this Handbook, so does not concern this article.

The process treatment of these steels is applied principally to sheet and strip for stamping and drawing and to parts made from such steels between drawing operations.

It is often necessary to process anneal drawn products between operations to relieve work strain in order to permit further working. This operation is usually carried out at temperatures between the recrystallization temperature, and the lower critical temperature. Its effect is to soften by recrystallization and grain growth of ferrite. It is desirable to keep the recrystallized grain size relatively fine and for that reason rapid heating and short holding time at temperature are desirable. The low temperatures also keep the scaling at a minimum. The customary practice is to discharge the parts from the temperature into air. If complete surface protection is desired, the material may be heated in liquid baths or controlled atmosphere furnaces.

A similar practice may be used in the treatment of low carbon cold headed bolts. Sometimes the strains introduced from cold working so weaken the heads that they break through the most severely worked portion at the slightest disturbance. Process annealing as described above is sometimes used to overcome this condition. The temperatures used are, as a rule, close to the lower critical. This results in considerable reduction of the normal cold drawn physical properties. A stress relieving treatment at about 1000°F. for cold headed bolts made from S.A.E. 1020 for the automotive industry retains much of the strength acquired in cold

*Prepared by the Subcommittee on the Heat Treatment of Carbon Steels. The membership was as follows: M. L. Frey, Chairman; E. O. Dixon, and T. A. Benton.

working and provides ample toughness. A more common practice is to combine a stress relieving treatment with an actual quench from the upper critical temperature or slightly above. This treatment produces physical properties which approach those of the cold drawn stock. A common quenching medium is a water solution of soluble oil. Its use produces two desirable results. First, the surface of the parts is given a pleasing black color which is accepted as a commercial finish and, second, the speed of the quench is slowed down to the point where extreme hardness is not produced and it is not necessary to temper the parts.

The heat treatment applied to machinery parts other than bolts and stampings sometimes consists of normalizing when high toughness is desired. Since the air hardening properties of these steels are low, the resulting tensile strength and yield point will be low. Annealing from above the upper critical temperature, followed by slow cooling is seldom used because it results in low strength and poor machinability. With special work, a drastic quenching as in water or 5% caustic followed by tempering is used to produce moderate strength and high toughness in parts of small section. The obtainable increase in strength, however, is not sufficient for general practice, so it is better to use a material with higher carbon steel or alloy steel.

Heat treatments to improve machinability are frequently employed. The generally poor machinability of the low carbon steels, except those containing sulphur or other special alloying elements, is due principally to the fact that the proportion of free ferrite to carbide is high. Additional factors are the form in which the carbide occurs and the distribution pattern of the carbide containing constituent. Because it is soft and ductile, ferrite is responsible for the tearing action of tools and the loading of metal on their cutting edges. Any treatment which distributes the carbide throughout the ferrite mass in such a way as to effectively break it up favors machinability. In the case of spheroidized steels, the distribution of free ferrite and carbide is the highest possible, and in this condition the machinability is poor in spite of a favorable distribution pattern. In fully annealed steels the distribution of free ferrite and carbide is more favorable because the carbide is present as pearlite, which occupies more volume, but the distribution pattern is poor. Normalizing improves this condition and therefore aids machining. Even though the as-forged structure varies considerably, the distribution pattern is usually good and steels in this condition machine with reasonable satisfaction.

The best machinability in steels up to 0.20% carbon is usually obtained by quenching the steel into mineral oil from 1500-1600°F. Since the rate of cooling is below the critical cooling rate, no martensite is formed and tempering is not required (with the exception of steels 1025 and X1025). This treatment improves machinability by improving the distribution pattern for ferrite and carbides.

Group II, S.A.E. Steels 1030-1050—Because of their higher carbon content, heat treating becomes of increasing importance when considering steels of this group. They are the most versatile of the carbon steels because their hardenability can be varied over a wide range by suitable control of the various factors.

Hardenability is an inverse function of the critical cooling rate¹; that is, a low critical rate produces high hardenability and a high one, low hardenability. The critical cooling rate may be defined as that rate of cooling through the transformation range which must be equalled or exceeded if complete hardening (martensitization) is to take place. A knowledge of the factors affecting this critical cooling rate may, therefore, be used to clarify the matter of hardenability. The relationships have not been fully defined quantitatively and the following discussion is in qualitative terms. In addition to those factors affecting the critical cooling rate, other pertinent points are presented.

1. Increasing the carbon content to the eutectoid point lowers moderately the critical cooling rate² but since we are primarily interested in controlling the hardenability of a steel with a narrow range of carbon, this factor is of secondary importance. The primary factor is that carbon alone up to about 0.55% determines the surface hardness obtainable,³ provided first, that all carbon is in solution in the austenite at the time of quenching, second that the critical cooling rate is reached or exceeded in quenching and, third that no appreciable austenite is retained after the quench. This statement applies regardless of the presence of other alloying elements. Maximum hardness is attained at about 0.55% carbon and further increase has no effect on surface hardness.

2. The effect of manganese, silicon and other alloying elements is to decrease the critical cooling rate,² thus making easier the attainment of full hardness as determined by the carbon and increasing the depth to which hardening will take

place in any particular section. In the carbon steels under consideration, manganese and silicon in moderate amounts are the principal hardening elements to be considered. Their effect is appreciable but not nearly as pronounced as the larger quantities found in some alloy steels.

3. Hardenability decreases as grain size number increases^{7, 10}; that is, fine grained steels harden less deeply than coarse grained steels.^{3, 4} It has been shown⁴ that fine grained steels have a higher critical cooling rate than coarse grained steels; therefore, any alloying element which reduces this rate will tend to offset the effect of fine grain. In the carbon steels manganese is frequently used for this purpose.

4. Normal steels harden more deeply than abnormal steels because of their lower critical cooling rate. Contrary to popular opinion, abnormality is not confined to fine grained steels. Both manganese and silicon are effective in counteracting abnormality.

5. Hardenability decreases as size of section increases.⁸ This effect takes place in two stages; first, there is a reduction in depth of hardening with little or no reduction of surface hardness; second, with further increase of size there is a marked reduction in surface hardness until finally no worthwhile hardening can be observed.

6. Depth of hardening increases as quenching temperature is increased from the upper critical point of the steel to a point well above commercial hardening temperatures. This effect is caused by the fact that increasing the temperature from which the piece is quenched increases the grain size and effective cooling speed of the quench. Surface hardness falls off slightly with increase of temperature after the grain coarsening temperature is reached.

7. Depth hardness increases as the severity (speed) of the quench increases up to the critical cooling rate. When that rate has been reached, there will be no further increase in surface hardness since this value is controlled solely by carbon content. Further increase in severity of quench may or may not result in increased depth of hardening, depending on the effect of other factors, principally manganese, silicon and grain size. It follows that the depth hardness of fine grained steels will be increased by increasing the severity of the quench and, conversely, the depth hardness of coarse grained steels will be decreased by decreasing the severity of the quench. It should also be kept in mind that increasing the speed of quenching beyond that necessary to produce the required hardness is usually of little value and often results in warpage and breakage.

8. The rate of heat removal in quenching is seriously affected by the surface condition of the work. Tightly adhering or heavy scale or soot or tightly adhering material from liquid baths prevent rapid transfer of heat to the quench, thus making more difficult and sometimes impossible the attainment of critical cooling speed and full surface hardness.

9. The rate of heating of parts for quenching has a marked effect on hardenability under certain conditions. In those cases where the structure is nonuniform as from severe banding or lack of proper normalizing or annealing, extremely rapid heating such as may be obtained in liquid baths will not allow sufficient time for diffusion of carbon and other alloying elements in the austenite with the result that nonuniform or low hardness will be produced. In the case of steels containing free carbides, for example, spheroidized material, sufficient time must be allowed for the solution of these carbides, otherwise the austenite at the time of quenching will have a lower carbon content than is represented by the chemical composition of the material and disappointing results may be obtained. For a case in which this condition is deliberately produced see the discussion under Group III.

10. From the above, it is evident that structure of the material prior to hardening has an important bearing on the hardenability.

For best physical properties after hardening and tempering, these steels should be either normalized or annealed before hardening. Parts made from bar stock are frequently not given any treatment prior to hardening but it is common practice to so treat forgings. Heating practice for these steels should be in accordance with the principle^{11, 12} given elsewhere.

Like the low carbon steels of Group I, these steels machine poorly in the spheroidized state. This may be improved, especially in the case of fine grained steels, by high normalizing temperatures such as the upper limits of the ranges in Table I. This high temperature treatment temporarily coarsens the grain, thus improving machinability. Upon subsequent treating the coarsening effect disappears and the steels again behave as fine grained materials.

Cold headed products are commonly made from these steels, especially those of lower carbon. Process treating before cold working is usually necessary because the higher carbon decreases the workability. In some cases normalizing or annealing above the upper critical is used but more frequently a spheroidizing treatment is used. The degree of spheroidization required will depend upon the application. After the mechanical operations are finished, the parts are heat treated by quenching and tempering.

These steels are widely used for machinery parts for moderate duty. When such parts are to be machined after heat treatment, the maximum hardness is usually held below 300 Brinell and is frequently much lower. When no machining except grinding is required hardnesses may go much higher.

The following gives the range within which the hardness of representative parts is usually found:

Name or Part	Grade of Steel	Brinell Hardness No.
Crankshafts	1040, 1045	228-286
Connecting Rods	1035, 1040	187-241
Wheel Flanges	1030, 1035	302-444
Steering Arms	1035, 1040	207-269
Shafts	1045, 1050	228-402
Front Axles	1035, 1040	196-269
Couplings	1030, 1045	207-321
Thrust Washers	1040, 1045	341-514
Wheel Lugs	1040, 1045	364-477

The selection of a quenching medium will vary with the steel composition, the design of the part, the hardenability of the steel and the hardness desired in the finished part. When the design of the part permits, the best combination of strength and toughness results from full hardening (martensitization) of the part followed by suitable tempering. In these steels this nearly always means water, brine or caustic soda quenching. Often the design is such that breakage will result from such quenching or the distortion limits will be exceeded and the mild oil quench, with its lower hardness and less complete retention of ferrite must be used. Considerable help may be had in such cases, from proper adjustment of chemical composition and from control of hardenability. The lower carbon steels, if fine grained and abnormal, are shallow hardening even when quenched in caustic while the higher carbon steels when coarse grained and normal, will give hardnesses of 450 Brinell when oil quenched in small sections and exhibit satisfactory hardening up to two in. dia. The wide range shown in the quenching temperatures in Table I is made necessary by the fact that a wide range of conditions must be met. It is not intended that such a temperature range should be used on any one part or under any given set of conditions. General practise is to use a suitable temperature within $\pm 10^{\circ}\text{F}$. The lower temperatures should be used for the X1300 series (high manganese) steels, light sections, coarse grained material or water quenching. Conversely the 1000 series (carbon) steels, heavy sections, fine grained material and oil quenching will require the higher temperatures.

A type of treatment finding considerable use is the light case hardening of many machinery parts. The material is heated to its normal hardening temperature in an activated bath and quenched into oil. The purpose of this treatment is to produce a superficial hard skin for wear resistance. Only low temperature tempering can be done on such parts, otherwise the surface hardness will be impaired. It is necessary to choose the degree of hardenability in relation to section such that the required degree of toughness is obtained in the as-quenched product. In applying such parts it must be borne in mind that the presence of the hard skin reduces their notch toughness below that which would be found if the skin were absent.

Many common hand tools such as pliers, open end wrenches, screw drivers and a few edged tools such as tin snips and brush knives are made from these steels. The cutting tools are necessarily water, brine or caustic quenched locally on the cutting edges, followed by suitable tempering treatments. In some cases the edge is time quenched severely, followed by oil quenching the remainder of the tool for partial strengthening. Pliers, wrenches and screw drivers, when made of these grades are usually quenched in water and suitably tempered. The quenching may be either local or complete.

Group III, S.A.E. Steels 1055-1095—The principal uses of steels of this group are heavy machinery parts, hand tools, cutting tools, and springs. The material and heat treatment for springs are covered elsewhere in this Handbook.

For heavy machinery parts such as shafts, collars and the like, steels S.A.E. X1055 and X1065 may be used either as normalized and tempered for moderate strengths or as quenched and tempered for higher strengths. Other steels in the list may be used but the combination of carbon and manganese in the two mentioned makes them particularly well adapted for such applications. In selecting any of these steels for such applications, it must be remembered that even with all hardenability factors favorable, these steels are essentially shallow hardening (as compared to alloy steels) because carbon alone, or in combination with manganese in the amounts involved here, does not promote deep hardening. Therefore, the sections for which such steels are suited will be definitely limited. In spite of this characteristic, the danger of breakage when treating such parts, especially when changes in section are involved is real and must be carefully guarded against.

Hand tools of many kinds such as open end wrenches, Stillson wrenches, hammers, mauls, pliers and screw drivers and cutting tools, both hand and power operated, such as hatchets, axes, mower knives and band knives, when made of carbon steels classed as commercial as opposed to tool grades, are made of steels in this group. The combination of carbon and manganese in the steels used may vary widely for the same type of tool, depending partly upon available equipment for manufacture and partly upon personal experience with or preference for certain combinations. In some cases, lower manganese content will be used. This is justified when it makes a particular carbon range easier to handle but it should be understood that in most cases a combination of lower carbon and higher manganese would serve just as well. An exception to this is the case of hand cutting tools which will be discussed later.

Forged parts should be either normalized or annealed, preferably the latter, first, because refinement of the forging structure is important in producing a first quality hardened product and, second, because the parts as they come from the hammer are too hard for cold trimming of the flash and for any machining operations. Ordinary annealing practice as given in the table, followed by furnace cooling to 1100°F. is satisfactory for most parts.

For hardening wrenches, except the Stillson type, screw drivers, pliers, and such tools, oil quenching, followed by tempering to the required hardness range is generally used. Even when no reduction of as-quenched hardness is desired, a stress relieving temper at 300-375°F. is desirable to prevent sudden service failures. In the case of Stillson type wrenches the jaw teeth are really cutting edges and are nearly always water or brine quenched to produce full hardness. The jaws may be either locally heated and quenched or the parts may be heated all over, the jaws locally time quenched for full hardness in water or brine and the entire part then quenched into oil for partial hardening of the remainder. In this way considerable structural strength is obtained.

Hammers must possess high hardness on the striking face and somewhat lower hardness on claws, if of that type. They are usually locally hardened and tempered on each end in accordance with their type. The striking face is always water or brine quenched. Satisfactory service depends upon getting the proper depth of fully hardened (martensitic) surface on this face, followed by a stress relieving temper at about 350°F.

Hand cutting tools, most particularly axes and hatchets, must possess high hardness and high relative toughness in their cutting edge as well as the ability to hold a keen edge. Since nothing is so effective as carbon in imparting the latter property, the carbon content is always higher than would be the case if hardness and toughness alone were to be considered. Many such tools are given an ordinary furnace anneal following forging, but in many cases they are prepared for hardening by spheroidization. This may be done as a separate operation following regular annealing but most frequently the refining and spheroidizing treatments are accomplished by quenching into oil from 1600°F. followed by tempering at 1250-1375°F. Heating for quenching puts all constituents into solid solution and quenching retains the carbon in a finely divided state from which condition spheroidization takes place rapidly at the temperatures specified. For hardening, such tools are usually heated in liquid baths to the lowest temperature at which the piece can be hardened and then brine quenched. The quick heating of the liquid bath plus the low temperature fails to put all of the spheroidal carbon into solution with the result that the cutting edge of the tool consists of martensite of lower carbon content than indicated by the chemical composition of the steel in which are embedded many particles of cementite. In this condition the tool is at its maximum toughness relative to its hardness and the embedded carbides promote long life of the cutting edge.

Agricultural implements make much use of the steels in this group. Braces, control rods, shafts and similar parts are often made of high carbon steels, untreated, in order to obtain increased strength at low cost. The principal heat treated parts are plow shares, moldboards, coulters, cultivator shovels, discs for harrows and plows, mower and binder knives, ledger plates and band knives. Those parts used for cutting or turning soil must have the ability to resist abrasion and be moderately tough. They are made from various combinations of carbon and manganese such that full hardening may be obtained. Frequently the cutting edges of plow shares and cultivator shovels are water or brine quenched to obtain high hardness. Plow shares, moldboards and cultivator shovels are often made from "soft center steel" which consists of a layer of dead soft material between two equally thick layers of high carbon steel. This material is rolled from specially cast composite ingots. Such parts are heat treated to produce high hardness in the outer layer, leaving the relatively soft interior layer to provide toughness. The final product is similar in physical properties to a case hardened part, in fact, these parts are sometimes case hardened.

The grass and grain cutting tools are usually made of S.A.E. 1090 or 1095 because of the effect of carbon in providing the desired long life edge. These parts are made from strip stock by blanking and no annealing is done except probably some process annealing by the rolling mills at or below the critical. Spheroidization is, therefore, only occasionally obtained. Hardening is done usually in continuous furnaces provided with fixtures that cause the pieces to be differentially heated on the cutting edges only. Upon discharge the parts are quenched all over in oil and tempered at a low temperature. Final hardness on the cutting edges is in the neighborhood of 55-60 Rockwell C.

In many applications of the steels in this group, hardenability is of considerable importance and must be adjusted to the needs of the individual case for best results. Heat treating tests on representative or critical sections are the most satisfactory method of determining hardenability.

A method of heat treating in which, instead of being quenched and tempered in the usual manner, the pieces are heated in the regular manner, put into a liquid bath maintained at an elevated temperature and allowed to transform there, is suitable for steels of approximately eutectoid composition. This method, which is covered by patents, is similar to the patenting of high carbon wire. It is particularly useful in producing a combination of high hardness and high toughness. At the present time it has been developed only to the point where it is suitable for light sections usually not over $\frac{3}{8}$ in. Since further discussion is beyond the scope of this article, it is suggested that those interested consult the original publications.^{4, 11, 12}

Composition and Heat Treatment of Carbon and Alloy Steel Castings*

Heat Treatment for Carbon Steel Castings

General—The following article applies generally to commercial castings for ordinary construction purposes, and not for special uses. Where authoritative specifications, as for example A.S.T.M. specifications, exist, the practice listed conforms to such specifications.

Chemical Composition—The range of chemical compositions considered in this article is given in Table I.

Table I
Chemical Composition

Class	Carbon	Manganese	Silicon	Phosphorus	Sulphur
Low carbon.....	below 0.20	0.50-1.0*	0.25-0.75	0.05 max.	0.05** max.
Medium carbon.....	0.20-0.50	" "	" "	" "	" "
High carbon.....	over 0.50	" "	" "	" "	" "

*A.S.T.M. specifications place an upper limit of 0.85% on manganese in castings for railroad use.

**A.S.T.M. specifications allow 0.06% sulphur in acid steel.

Cooling and Cleaning Castings After Pouring—After pouring, castings are usually allowed to cool in the mold to a temperature below the critical range. Cast steel in the unannealed state tends to be tender and brittle. This is especially true of large sections and higher carbon contents and such castings are often shaken out above the critical temperature, partially cleaned and charged to the annealing furnace just below red heat. This procedure is to prevent possible cracking from stresses set up by cooling.

After shaking out and before heat treating, the castings should be cleaned sufficiently to insure thorough and even penetration of heat during heat treatment. If gates and risers are to be nicked and broken off this should be done before heat treating while the steel is less ductile. If the gates and risers are to be removed by flame cutting, this should be done before heat treating in order that the hardened zone adjacent to the kerf may be softened. High carbon steels should be flame cut while still hot.

When thus prepared the castings are subjected to one or more of the heat treatments described below.

Single Normalizing or Single Full Annealing—The castings are placed in a furnace and heated to the temperature given in Fig. 1. Uniformity of heating is important and the rate of heating should be so governed as to insure a reasonable degree of uniformity. This is especially important for heavy sections in order that there will be the minimum lag in temperature between the surface and center.

The purpose of the annealing is twofold: (1) To produce an allotropic change which causes the steel to recrystallize, thus breaking up the very large crystals formed during freezing; (2) To homogenize, or correct by diffusion, the microsegregation of constituents, sometimes known as dendritic segregation, which always occurs during the freezing of an impure liquid such as steel.¹

Fig. 1—Temperature range for the heat treatment of steel castings. The lines bounding the "range" indicate the normal lower and upper limits for annealing carbon steel castings with carbon from 0.15-0.80%.

*Prepared by the Subcommittee on the Heat Treatment of Steel Castings. The membership of the subcommittee was as follows: C. E. Sims, chairman; J. H. Hall, H. D. Browne, H. D. Phillips, H. B. Knowlton, and W. C. Hamilton.

¹See page 3 for definition of terms.

²Although complete homogeneity by diffusion is desired and attempted such a state is probably never attained, owing to the slowness with which some elements, such as manganese, silicon, and phosphorus diffuse. It is almost certainly true, nevertheless, that the dendritic structure obtained by macroetching an annealed steel is due to pseudo-morphs of the dendrites that once existed.

The recrystallization is completed as soon as the critical temperature range is passed, but the rate of diffusion is rather slow at this temperature. The rate of diffusion increases rapidly with the temperature, and in order to save time an annealing temperature somewhat above the upper critical range is used. Since both the rate and extent of grain growth also increase rapidly with temperature, too high a temperature is not desired. Therefore, a compromise temperature, which is seldom more than 200°F. above the upper critical range, but which will give diffusion in a reasonable time without excessive grain growth, is used.

Since the size of the primary crystals and, therefore, the degree of microsegregation are increased by the slower freezing of heavy sections the time required for diffusion will vary with the section of the casting. Very light castings which are practically chill cast can be homogenized in less than 1 hr. For heavier sections, experience, backed by some experimental evidence, has dictated a rough guide which is usually stated as 60 min. per in. of heaviest section.

This rule requires some modification. While 1 hr. is usually enough for a 1 in. section the time is not critical. The size of the crystals does not vary as a linear function of section but apparently reaches a maximum in sections somewhere between 6 and 12 in. It is doubtful, therefore, whether any casting however big is benefited by annealing more than 10-12 hr. This time, called the holding time, should begin when the castings are uniformly heated to the annealing temperature. Providing the temperatures are not too high (Fig. 1) overtime heating causes little change in the physical properties.

Normalizing vs. Full Annealing—In general, normalizing produces higher yield and ultimate strength than full annealing. Ductility is approximately the same after either treatment, but normalizing often gives higher impact resistance. There is less separation of ferrite and pearlite in normalizing. Full annealing gives a softer steel and greater freedom from stresses, but ties up furnace equipment for a longer time.

Double Treatment—As was pointed out in regard to single annealing the conditions favorable to rapid and complete diffusion and fine grain are quite dissimilar. Inasmuch as both homogeneity and fine grain are highly desirable for optimum physical properties in a steel, a double heat treatment is often employed. For the first treatment temperatures and times similar to those advocated for single annealing may be used but sometimes higher temperatures or longer times are used. In this treatment homogeneity due to diffusion of the contained elements is approached, but, unless the steel is resistant to grain growth, the grain structure is made relatively coarse.

The second treatment is designed only to refine the grain and the temperature used is just above the upper end of the Ac₁ range. Because grain growth is partly a function of time, the time used in the second treatment should be just long enough to insure uniform heating of the castings to the desired temperature.

Tempering or Stress Relief Annealing—After the normalizing treatment (seldom after full annealing) a treatment below the lower critical temperature may be given at the discretion of the operator. This may be for one or both of the following purposes: (1) To remove stresses set up in the castings by nonuniform cooling; and (2) To improve the ductility and impact resistance of the steel with some sacrifice of strength.

For the removal of stresses, temperatures below about 500°F. are of little value and temperatures above 1000°F. are unnecessary. As a rough guide, it has been found that a temperature of 750°F. will reduce the stresses approximately 50% and 1000°F. will reduce them over 90%.

Except in special cases, the time the castings are held at the tempering temperature should be at least sufficient to insure complete equalization of the temperature throughout the heaviest section of the casting. After reaching the temperature a common holding time for light and medium weight castings is 2 hr. Times of 5-10 hr. are used for heavy castings with sections a foot or more in thickness.

Ordinarily temperatures below 1000°F. have no effect on strength or ductility in a normalized steel. Temperatures above 1000°F. up to 1300°F. progressively lower the strength and increase the ductility in moderate degree. The effect of such temperatures is also progressive with time but at a constantly diminishing rate. Holding times over 2 hr. are probably of little value.

Oil and Water Quenching Steel Castings—When exceptional physical properties, high degree of structural refinement, and resistance to wear are required, heating

and quenching will greatly assist in producing the desired results. When the carbon content of the castings is above 0.30% or when the manganese is high (0.85-0.95%), quenching and tempering are especially effective in producing these requirements. If quenching is for hardening it should be borne in mind that carbon steels are shallow hardening and that, in the medium carbon ranges even with water quenching, only a thin shell or case will be effectively hardened. The higher carbon steels, of course, are deeper hardening. Quenching for the purpose of toughening is not confined to light sections.

For maximum properties and to minimize the danger of cracking, it is recommended that castings should be annealed or normalized before quenching, although for some work this is not essential. The argument for this is similar to that for double normalizing. A coarse grained martensite is less tough and more apt to crack than one that is fine grained.

When water is used as the quenching medium, the temperature of the water should preferably be maintained at 125-150°F. for the higher carbon contents. With carbon under 0.40% the quenching may be more drastic.

When the size and design of the castings are such that quenching might cause cracking if kept in the water or oil until cold, the castings should be removed from the quenching bath when they have become black, but are still hot enough to dry the water quickly; or in the case of oil, the castings should be hot enough to cause the oil to smoke freely on the surface of the casting. This temperature should not be less than about 400°F.

Differential Quenching—Where it is desirable that only certain portions of the casting shall develop the qualities secured by liquid quenching, differential quenching is followed. In this process certain sections are subjected to a liquid quench, either by dipping or spraying, the rest of the casting being protected from the quenching effect. This quenching is often controlled by a stop watch and requires careful attention. The quenched portions are tempered in some cases to give the desired properties.

Tempering—After quenching, the castings should be tempered immediately. When the load is charged while hot into the tempering furnace, the temperature of the furnace should be approximately the same as that of the castings (about 700°F.). The tempering temperature ranges from 800-1250°F., depending upon the physical properties desired. The higher the temperature, in this range, the lower will be the strength and hardness and the higher will be the ductility and toughness.

The quenching and tempering temperatures are given in Table II.

Table II
Quenching and Tempering of Carbon Steel Castings

Carbon Range	Quenching Temp., °F.	Time at Heat	Quenching Medium and Temp., °F.	Tempering Temp., °F.	Tempering Time at Heat
0.15-0.30	1600-1650	¼ hr. for every in. of dia. or thickness	Water at 70	800-1250*	At least 2 hr.
0.30-0.40	1550-1600	¼ hr. for every in. of dia. or thickness	Water at 125	800-1250*	At least 2 hr.
0.40-0.60	1500-1550	¼ hr. for every in. of dia. or thickness	Water at 125 or oil	800-1250*	At least 2 hr.

*These temperatures are based on the assumption that the castings were first annealed.

*See text for tempering.

Notes on the Process—With some castings that have had considerable machine work performed on them, such as heavy duty gears, it is often considered advisable to remove the machining stresses by heating the castings slowly and uniformly to a temperature of 400-600°F., then cooling in air.

Castings should be charged into the furnace in such a manner that lighter castings will be protected from the heat of the furnace by the heavier castings. Should the castings be of similar section, care must be exercised not to heat too long those on the outside of the charge before the inner ones have reached the annealing temperature.

When charging the furnace, the castings should be piled loosely so that the hot gases will have free circulation throughout the charge. To further insure free circulation of the gases, it is advisable to pile the castings a few inches above the floor of the furnace and so permit free circulation of the hot gases. When cooling

from the normalizing temperature, this practice of piling the castings on racks also insures free circulation of the air.

A sufficient number of thermocouples should be used and so arranged in the furnace and, if possible, in the charge of castings, that the desired temperature can be maintained at the top, center, bottom, and sides of the charge.

Steel castings should be grouped for heat treatment, so that the carbon content of the entire charge falls within one of the carbon ranges given in the recommended practice.

As a basis for determining the physical properties of the metal in the casting, it is commercial practice to use test coupons cut from separately cast blocks or attached to the castings. When attached to the casting they should be so placed that they are properly fed and represent, as nearly as possible, the inherent properties of the metal. Test coupons should be heat treated with the castings they represent.

To check the heating operation and to obtain closer control of the temperature, it is sometimes the practice to distribute several test specimens, for fracture inspection, throughout the charge of castings. The cross sectional dimensions of the specimens should represent the largest cross section of the castings, and the carbon content should be approximately the same as the castings being heat treated. After completion of the heat treatment, an examination of the fractures of the specimens for grain refinement indicates the uniformity of heat distribution without destroying a casting for fracture inspection. This practice is obviously impracticable with very heavy sections.

Table III
A.S.T.M. Specifications for Properties of Cast Carbon Steel

Grade	Tensile Strength, psi.	Yield Strength, psi.	Elong. in 2 in., %	Red. of Area, %
A-1	60,000	30,000	22	30
A-2	60,000	30,000	26	38
B	70,000	38,000	24	36
H	80,000	43,000	17	25

Of the above grades all but A-1 require annealing. Grades A and B cover castings for railroad and miscellaneous uses. Grade H does not apply to railroad use.

Composition and Heat Treatment for Alloy Steel Castings

General—This article is designed to cover the heat treatment of alloy steel castings and applies generally to commercial alloy castings for ordinary construction purposes and not for special uses.

Chemical Composition—Only the so-called low alloy steels are considered in this section. In such steels the carbon range is from 0.15-0.60% and the total alloy content is less than 5%. There are about 75 different alloy combinations that have been recommended or used that fall in this classification. Some have but one special alloying element while others may have as many as four. The list is being constantly revised. Typical compositions and physical properties are shown in Table IV.

Cooling and Cleaning of Castings—The lighter section alloy steel castings should be allowed to cool in the molds to a temperature below the critical range, then shaken out and cleaned of adhering sand before heat treatment. Gates and risers are usually removed by flame cutting while the castings are still warm to avoid the formation of small cracks adjacent to the kerf.

Because of the fact that high carbon and alloy steel castings tend to be weak and brittle before heat treatment and as the stresses set up by unequal cooling are sometimes sufficient to fracture them, large castings often are not allowed to cool in the mold below red heat. Instead they are shaken out quite hot, roughly cleaned of sand, gates and risers removed by flame cutting, and the castings charged to the annealing furnace when just below red heat, or at least above 500°F.

If the castings are to be given more than one heat treatment the gates and risers are often removed by flame cutting after the first treatment, but in any case it is preferably done while the castings are hot.

Heat Treatment—Heat treatments may be classified as follows: Full annealing, normalizing, quenching, and tempering.

Broadly speaking, the benefits of alloys in steel are obtained through their effect on the response to heat treatment, such as a slower critical cooling rate, or resistance to softening during tempering. Full annealing, therefore, would fail to take advantage of these benefits and is seldom used except as a first treatment, to be followed by normalizing or quenching. Probably the main advantage of full annealing is to put the steel in a condition where it is easily machined.

Whether an alloy steel should be normalized or quenched is largely determined by (1) the type of steel and (2) the use to which it is to be put. Some alloy steels attain the optimum combination of properties through normalizing. This is especially true of those steels that have great resistance to grain growth, the so-called fine grained steels.

Many alloy steels require quenching and tempering to develop their best properties. Quenching is also used when high hardness is desired. Some castings which have intricate design or large differences of section are not quenched because of danger of cracking or warping. The steel should be selected to fit the casting and if hardness is desired in a casting that cannot be safely quenched, an air hardening composition may be used.

Normalizing—Both single and double normalizing treatments in general follow the procedure given for carbon steels, and have similar objectives. In the first treatment temperatures (for a given carbon content) may be somewhat higher and times of holding may be longer than for carbon steels because the alloy constituents diffuse somewhat more slowly than does carbon.

Temperatures for the first anneal of from 1550-1700°F., depending on the carbon content, are satisfactory for all the steels in this classification with the possible exception of some molybdenum steels which are sometimes annealed as high as 1750°F. The time of 1 hr. per in. of section is a good guide, subject to the modifications listed for carbon steels.

In the second normalizing the objective is grain refinement and the temperatures used should be from 25-50°F. above the end of the A_c range.* The time should not be longer than required to insure uniform heating and complete solution of carbide in the gamma iron. Some of the alloy carbides such as molybdenum carbide are less easily soluble than is iron carbide and require a longer time for solution. In most cases $\frac{1}{4}$ -1 hr. after reaching uniform temperature is sufficient.

Quenching—Quenching of alloy steels is preferably but not necessarily preceded by a normalizing or full annealing treatment to avoid the coarse grain resulting from the long soak otherwise necessary to attain homogeneity.

After such proper annealing, the castings should be heated slowly and uniformly to the quenching temperature, which is similar to that used for a second normalizing treatment, or 25-50°F. above the A_c range. The time of holding should also be the same as for normalizing.

When water is used as the quenching medium, the temperature of the water should preferably be maintained at 125-150°F., especially for the higher carbon steels.

When the size and design of the castings are such that quenching might cause cracking, if kept in the water or oil until cold, the castings should be removed from the quenching bath while still hot enough to dry the water quickly, or in case of oil, the castings should be hot enough to cause the oil to smoke freely on the surface of the castings. They should be charged immediately into a warm tempering furnace.

Differential Quenching—For information on this practice see article on carbon steel castings.

Tempering—Alloy steel castings should be reheated for tempering as soon as possible after quenching. It is a very general practice to temper normalized alloy castings also but the stresses in the normalized steels are naturally of far less magnitude and it cannot be said that the tempering treatment is necessary for all compositions and designs after normalizing.

The purpose of tempering is to relieve the stresses and brittleness caused by quenching or normalizing and to moderate the hardness, that is, to toughen the material. The temperature to be used depends upon the hardness and physical properties desired. Usually the higher the temperature, up to the beginning of the critical range, the softer and more ductile the steel. For maximum hardness and strength a tempering temperature only sufficient to relieve excessive stress is used.

*The margin used will depend somewhat on the uniformity of the furnace. An average temperature that will insure the lowest temperature above the A_c range should be used.

Table IV
Approximate Compositions and Mechanical Properties of Low Alloy Steels

*The ranges given are not accidental spreads, and the higher strengths and lower ductilities go with the higher end of the composition range and vice versa.

This is usually from 350-450°F. The maximum tempering temperatures depend on the lower critical temperature but should usually not exceed 1250°F.

The softest and most ductile state is usually obtained by heating just below the critical range for a long period of time, that is, spheroidizing.

Except in special cases, the time the castings are held at the tempering temperature should be at least sufficient to insure complete equalization of the temperature throughout the heaviest section of the casting. After reaching the temperature a common holding time for light and medium castings is 2 hr. Times of 5-10 hr. are used for heavy castings with sections a foot or more in thickness. The discussion on tempering carbon steel castings applies as well to alloy steel.

Uses—The alloy steels listed possess desirable combinations of hardness, strength, and toughness not obtainable with carbon cast steel. The castings are used for locomotive frames, gear blanks, dies, stamps, crusher jaws, pinions, car wheels, shovel teeth racks, chain, valves and fittings, and caterpillar treads. The selection of the alloy depends upon the service required.

Due to their higher physical properties it is possible to obtain greater strength for a given cross section than with carbon steel castings. These alloys, therefore, find a particular application where reduction of weight is important, and where high stresses are encountered.

Notes on the Process—General comments on carbon steel castings apply equally to alloy steel castings.

The straightening of castings is best done while they are uniformly heated to a temperature above 500°F. This operation can be done while the castings are cooling from the normalizing treatment, while heated for tempering, or after a special heating for this purpose.

The physical properties obtained by heat treating alloy castings are destroyed by the local application of heat, such as in welding, flame cutting, or hot straightening.* These operations produce dangerous local disturbances of grain structure, hardness, and excessive stresses. Castings should, therefore, be retreated after such practice, although in some cases a strain relieving treatment will suffice.

The rate of cooling in the normalizing practice is merely relative, depending upon the size of the charge and of the castings. The smaller the load or the lighter the sections, the more drastic the cooling, and therefore, the higher the physical strength. The ductility is not affected materially except for the more extreme changes of cooling rate.

It is commercial practice to use test specimens cut from a separately cast block or from test coupons attached to the casting as a basis for determining the physical properties of the castings. Test pieces or test coupons should be heat treated with the castings which they represent.

*This refers to local heating as with a torch for straightening or bending and not to the regular straightening done while the casting is heated uniformly to a temperature of 500-900°F.

Composition and Heat Treatment of Plain Carbon Steel Gears*

General—This article covers the selection of steel and the heat treatments for gears and sprockets made from plain carbon steel bars or forgings. Because of the wide diversity in the size and service application of gears, it is impossible to give detailed practices applicable to all cases.

All the temperatures recommended in this article refer to the temperature of the stock and not to the furnace temperature.

The steels given in Table I are suitable for gears and sprockets requiring only a moderate degree of strength and wear resistance. Their cost is less than that of alloy steels, and the cost of machining these steels is less than that of medium carbon alloy steels. The strength, hardness, and toughness are somewhat lower than that obtainable with the alloy steels.

It is recommended that the temperature of the furnaces for all heating operations, including the forging furnace, should be under proper pyrometric control.

Table I
Chemical Composition of Carbon Steels for Gears

S.A.E. Steel Nos.	C	Mn	P Max.	S Max.
1035	0.30-0.40	0.60-0.90	0.045	0.055
1040	0.35-0.45	0.60-0.90	0.045	0.055
1045	0.40-0.50	0.60-0.90	0.045	0.055
1046*	0.40-0.50	0.40-0.60	0.045	0.055
1050	0.45-0.55	0.60-0.90	0.045	0.055

Note—A silicon content of 0.15-0.30% is optional. The total of the nickel and chromium content must not exceed 0.20%.

*This is not a regular S.A.E. Steel.

Selection of Material—The chemical compositions of the steels commonly used are given in Table I.

The higher the carbon and manganese content of the steel, the greater will be the surface hardness and the penetration of hardness with any given speed of quenching. As a result, under any given quenching conditions, the higher carbon gears will have more tendency to distort and crack in treatment and to show less shock resistance after treatment. The smaller the gear and the faster the quench the lower must be the carbon and the larger the gear and the slower the quench, the higher must be the carbon. The mill practice and grain size of the steel likewise affect the hardness obtained and the hardness penetration with any given speed of cooling.

Steels 1035 and 1040 are commonly hardened by quenching in water, brine, or caustic solution. Steel 1045 may be water or oil quenched. When cracking in quenching is feared because of the design or the speed of quenching, steel 1046 is recommended. This steel is less prone to quenching trouble because the combined carbon and manganese content is less than 1.10%. Steel 1050 is primarily an oil quenching steel.

Forging—For forging, the bars should be heated to a temperature of 2100-2350°F. The forging temperature is governed by the amount of work to be done. The finishing temperature is important and should be 1600-1850°F.

The upsetting method is preferred because it gives proper grain flow, stronger gears, and less distortion in heat treatment. The upsetting may be accomplished in an upsetting machine or by hammering forgings in such a way that the direction of the blow is parallel to the grain flow of the bar before forging. Where high strength and minimum distortion are not essential, other methods of forging are permissible.

Normalizing and Annealing—In general it is recommended that all forgings should be normalized or annealed to refine the coarse structure produced by the

*Prepared by the Subcommittee on the Heat Treatment of Gears. The membership of the subcommittee was as follows: W. E. Jominy, Chairman; Fred Young, Scott Taylor and H. B. Knowlton.

forging temperature. This treatment will minimize the distortion in subsequent heat treating operations and improve the machinability. When cutting gears from bar stock, annealing or normalizing of the bar stock may be advisable in some cases, but is frequently unnecessary.

The recommended temperatures for normalizing and annealing are given in Table II. The cooling rate depends upon the size of the gears, the carbon content, and the hardness desired. In general plain carbon steel forgings are considered machinable in the normalized condition, although full annealing may improve the machinability.

Table II
Heat Treatment for Carbon Steel Gears

S.A.E. Steel Nos.	Normalizing After Forging, °F.	Annealing After Forging, °F.	Quenching, °F.	Temp., °F.
1035, 1040, 1045, 1046, 1050.....	1650-1750	1575-1650	1500-1550	350-850

When parts are large or the service required is not severe, normalizing or annealing may be the final heat treatment. A variation of these processes called "stack annealing" consists of piling the pieces as they come from the forging hammer or press and allowing them to cool.

Hardening—The gears should be heated uniformly to the temperature given in Table II and under conditions which do not scale, carburize, or decarburize.

The exact hardening temperature depends upon the analysis of steel, the thickness of the section, and the quenching medium employed. The higher the carbon and manganese content and the more severe the quench, the lower should be the quenching temperature. For any given steel and quenching medium, the heavier the section the higher should be the quenching temperature. To help eliminate distortion the lowest quenching temperature, consistent with the other conditions, should be used. When the carbon and manganese are at the high limit in steel 1050, temperatures as low as 1475°F. may be used and when the carbon and manganese are at the low limit in steels 1045 and 1046 temperatures as high as 1575°F. may be required.

Quenching—For quenching these steels, four methods are available as follows:

1. **Oil Quenching**—Oil quenching produces the lowest and shallowest hardness and the least distortion of any of the methods. Where sections are thin, or the carbon and manganese content high, or the least distortion possible must be obtained, this quench should be used. It is not generally suitable for heavy sections. It is common practice to have the temperature of the oil bath somewhere between 90 and 130°F.

2. **Water Quenching**—Quenching in water is applicable to most sections. Cold water quenching produces higher hardness but increases the danger of distortion and cracking. To withstand such quenching, the sections must be reasonably uniform. A combined carbon and manganese content above 1.10% increases the hazard. The heavier and more uniform the section and the lower the carbon and manganese contents, the more drastic may be the quench.

Quenching in warm water produces results intermediate between that of cold water and oil quenching. The danger of distortion and cracking, and the degree and penetration of hardness produced, decrease with increase of the temperature of the water. Bath temperatures above 130°F. are not usually recommended.

3. **Time Quenching**—Time quenching in water is used in connection with those parts which, because of either composition or design, cannot be completely quenched in water. The operation is carried out by allowing the piece to remain in the quench only until such time as it contains enough residual heat in the center of the heavier sections to reheat the entire part to a temperature approaching that used for tempering. At this point the piece is withdrawn from the quench and allowed to cool in the air until the residual heat has been distributed as evenly throughout as possible. After this it may be cooled in any convenient manner. The use of automatic devices for timing the quench and ejecting the gear is desirable. If the time quenching is carefully done and the hardness range on the finished gear is not too close, the tempering operation may be omitted, but it is safer to temper the gear the same as if completely quenched.

4. *Caustic Soda Solution*—A very severe quench is obtained by using a water solution containing a minimum of 4% caustic soda by weight. Such a quenching bath will operate satisfactorily up to 130°F. When used warm it is less likely to produce cracks than a water quench but at the same time it produces a high and deep hardness in the treated parts. This quench is of particular advantage when sections are heavy or the steel has a tendency to harden erratically in other quenching baths.

5. *Quenching from Cyanide*—A satisfactory gear can be made from 1010 steel with a 0.002-0.010 in. cyanide case. Where a deeper case is desired an activated cyanide bath may be used. A deeper case may also be obtained by carburizing. Cyanide hardening improves wearing surfaces. For example, if steel 1045 is quenched in oil from a cyanide bath, a file hard and serviceable gear should be obtained.

When small or finer pitched teeth necessitate the lower carbon steels, they should be given the cyanide treatment. The low carbon steels do not produce a good tooth finish. The quenching temperatures indicated in Table II should also be followed when heating in cyanide.

For 1010 to 1030 steels, the minimum cyanide bath temperature should be 1550°F. and in all cases above the A_c critical point.

Tempering—Tempering consists of reheating the gears to some temperature below the critical temperature of the steel in order to relieve strains, reduce hardness, and induce toughness. These results are accomplished simultaneously and are increased in degree with increase of time and temperature. All sections should be brought to the proper temperature and held for 15 min. to several hr., depending upon the size and type of gear.

The tempering temperature used will be governed by the hardness required in the finished gear, by the reaction of the parts to the quench, and by the peculiarities of the mill heat of steel from which the gears are produced. Because the reaction to quenching varies in different mill heats, there will be a variation in the hardness produced. There may also be a variation in the response of some heats to tempering. These conditions necessitate a variation in the tempering temperature in order to produce gears within any specified hardness range.

In Table II a tempering range of 350-850°F. is given. Tempering at temperatures above 850°F. will aid machining operations performed after heat treating, but will reduce the surface hardness below that usually required on heat treated gears.

Hardness—Because of the diversity of application, gears are used over the entire range of hardness that is obtainable in the material. It is, therefore, impossible to recommend hardness limits, but for any specific part a hardness range as narrow as practicable should be specified.

Testing—It is recommended that two teeth 90° apart be selected for hardness testing.

Periodic tests to determine tooth strength, fracture and microstructure are valuable in safeguarding the quality of the product.

Composition and Heat Treatment of Oil Hardening Alloy Gears*

General—This article covers the process to be followed in the heat treatment of oil hardening gears. It is recognized that the size, composition, and type of gears govern entirely the heat treating process. This article, therefore, pertains only to gears of approximately the size of automotive transmission gears.

All the temperatures recommended in this article refer to the temperature of the stock and not to the furnace temperature.

Chemical Composition—The alloy steels most commonly used for gears, together with their chemical compositions, are listed in Table I.

Table I
Approximate Chemical Composition

S.A.E. Steel Nos.	C	Mn	Cr	V (Min.)	Ni	Mo
2345	0.40-0.50	0.60-0.90	3.25-3.75
3140	0.35-0.45	0.60-0.90	0.45-0.75	1.00-1.50
3150	0.45-0.55	0.60-0.90	0.45-0.75	1.00-1.50
3250	0.45-0.55	0.30-0.60	0.90-1.25	1.50-2.00
3440	0.35-0.45	0.30-0.60	0.80-0.95	2.75-3.25
4145	0.40-0.50	0.60-0.90	0.80-1.10	0.15-0.25
4640	0.35-0.45	0.50-0.80	1.65-2.00	0.20-0.30
5140	0.35-0.45	0.60-0.90	0.80-1.10
5150	0.45-0.55	0.60-0.90	0.80-1.10
6140	0.35-0.45	0.60-0.90	0.80-1.10	0.15
6150	0.45-0.55	0.60-0.90	0.80-1.10	0.15

Grain Size and Hardenability—It is a common practice to control the grain size as measured by the McQuaid-Ehn test. Since this test is used to indicate the depth hardness characteristics of steel, it is often desirable to measure this property directly by some form of hardenability test.

Forging Temperature—The steels considered in this article should be forged or upset between 2100 and 2350°F., and it is recommended that the temperature of the forging furnaces should be automatically controlled with pyrometers. It is suggested that finish forging temperature be not lower than 1800°F.

Heat Treatment After Forging and Before Machining—To eliminate forging structure and to obtain desirable machining properties, gear blanks should be normalized and annealed. These heat treatments are given in Table II.

Table II
Normalizing and Annealing After Forging

S.A.E. Steel Nos.	Normalizing		Annealing ¹	
	Temp., °F.	Cool in	Temp., °F.	Cool in
2345	1650-1750	Air	1500-1550	Furnace at 50° per hr. to 900°F.
3140	1650-1750	Air	1500-1550	Furnace at 50° per hr. to 1000°F.
3150				
3250				
3440	1600-1750	Air	1500-1550	Furnace at 35° per hr. to 750°F.
4145	1650-1750	Air	1550-1800	Furnace at 50° per hr. to 1100°F.
4640	1650-1800	Air	1550-1800	Furnace at 50° per hr. to 900°F.
5140	1600-1750	Air	1550-1600	Furnace at 50° per hr. to 1100°F.
5150				
6140				
6150	1650-1750	Air	1550-1800	Furnace at 50° per hr. to 1100°F.

¹When the normalizing is omitted the annealing temperatures should be raised 40°F.

It is common practice to combine these treatments by a so-called cycle treatment consisting of heating to the normalizing temperature, rapid furnace cooling

*Prepared by the Subcommittee on the Heat Treatment of Gears. The membership of the subcommittee was as follows: W. E. Jominy, Chairman; Fred Young, Scott Taylor, and H. E. Knowlton.

to the critical range at approximately 200-250°F. per hour, and holding in the critical range until a proper structure is developed, usually requiring several hours, then furnace cooling to the temperature indicated in Table II.

After these heat treatments, the Brinell hardness number should be between 187 and 207. However, the Brinell hardness is not always indicative of good machining qualities, so microscopic inspection should show lamellar pearlite with a minimum amount of free ferrite or spheroidization.

Heat Treatment of Finished Machined Gears—After machining and cutting the teeth, the gears are hardened and tempered.

Heating for Quenching—The gears are heated slowly and uniformly to the quenching temperatures given in Table III, and held for sufficient time to assure complete and thorough penetration of heat. The heating medium should be so selected that scaling and decarburizing are held to a minimum.

To prevent excessive wear, and to produce a file hard surface, it is recommended that the gears should be heated in a medium (such as cyanide) or in an atmosphere producing a light carburized case; otherwise, the gears should be dipped into a medium such as cyanide after heating.

Quenching—The gears are quenched from the quenching temperature in oil as indicated in Table III. The quenching oil should be maintained constant within a suitable temperature range with a minimum variation consistent with the grade of oil used. It is common practice to keep within the temperature range of 90-130°F.

The best results are obtained by free circulation of oil around the gear being quenched. The formation of gas pockets should be avoided. In some cases special quenching fixtures are advantageous in producing rapid and uniform cooling, which eliminates distortion. The speed of cooling depends somewhat upon the rapidity of circulation of the oil.

Table III
Heating, Quenching, and Tempering of Gears

5150	1480-1520	Oil	400-450
6140	1500-1540	Oil	400-450
6150	1480-1520	Oil	400-450

¹If the gears are quenched from liquid heating media the temperature may be dropped 20°F.

Tempering—After quenching, the gears are reheated to the temperature given in Table III and held for at least ½ hr. For tempering, either a liquid or a circulating air heating medium is satisfactory.

Notes About the Process—Upset gear blanks produce teeth of uniform strength all the way around, whereas, pegged out flats when drop tested usually reveal strong teeth on two sides of the gear and weak teeth on two sides between the strong teeth.

Inspecting and Testing—At least two teeth 90° apart on every gear should be polished and tested for hardness. After quenching and tempering, the Rockwell hardness should be C-52-C-57. Special fixtures are of advantage for obtaining the hardness tests.

Specimens should be broken periodically under a drop hammer to check up on the forging and heat treating methods.

Cleaning—It is recommended that after quenching the gears should be properly washed to remove all oil before tempering, and that after tempering they should be cleaned by a suitable process.

Heating, Forging, Annealing, and Normalizing Locomotive Forgings*

Introduction—This article is to be used as a guide in the manufacture and heat treatment by annealing or normalizing of locomotive forgings, such as locomotive driving and traller axles, crank pins, main and side rods, piston rods, and similar forgings. The heat treatment of certain classes of such forgings by quenching in a liquid medium followed by tempering, which may also be done, is not covered by this article.

Heating Billets for Forging—As rapid heating may produce internal ruptures, care must be taken to avoid it, particularly from the low temperatures. Ample time should also be given for the heat to penetrate uniformly and thoroughly into the billet before forging. The actual heating time required will depend on the type of steel and the equipment and methods used for heating.

Cold billets should not be charged into a hot furnace. Billets that have been stored outdoors, particularly during winter months, should be brought into the shop for a warming period of 10-12 hr. before being charged into the furnace for heating.

Preheating Forging Billets—It is good practice to preheat the billets. This is best done in a separate furnace or one with a preheating chamber. If such a furnace is not available, the billets can be charged into a forging furnace after the operations for the day are completed, and the furnace has been cooled down to a dull red. The billets will absorb the furnace heat and by the next morning will be preheated to a temperature of several hundred degrees Fahr. They are then ready for direct firing, which should proceed slowly. When a separate furnace is available for preheating, the billets are charged into the cold furnace and brought up slowly and uniformly to a temperature of 1100-1200°F. The time required to heat to this temperature should be approximately three-quarters of an hour to an hour per inch of least thickness.

To avoid loss of heat, the billets should be transferred quickly from the preheating furnace to the forge heating furnace. As the danger of rupturing the billets has been practically eliminated by preheating, the forging furnace can be at considerably higher temperature than the preheated billets. Raising the preheated billets to the forging temperature is carried out with the usual precautions to insure uniform heating and thorough penetration of the heat. The minimum time required to bring preheated billets from a temperature of about 1100°F. to the forging heat (2100-2200°F.) is approximately one-half hour to one hour per inch of least thickness. For billets of various thicknesses, the following heating schedule is typical:

8x 8 in.....	3 hr.	10x10 in.....	4 hr.	12x12 in.....	5 hr.
14x14 in.....	6 hr.	16x16 in.....	7 hr.	18x18 in.....	9 hr.
12x 6 in.....	3 hr.	14x 8 in.....	4 hr.	20x 8 in.....	4 hr.

Forging Temperatures for Billets—The proper forging temperature for both carbon and alloy steel billets, of the types generally used for locomotive forgings, is 1900-2100°F., which is an orange to yellow heat. Overheating and uneven heating must be avoided, as both are sources of forging ruptures. It is desirable to have the heating furnace under pyrometric control, preferably by thermocouples.

The temperature at which the forgings are finished will be determined by the initial forging temperature, and by the temperature lost during forging, which depend respectively on the size of the forging and on the amount of work required to shape the forging from the billet. Generally, they are finished at a temperature of 1500-1700°F. Lighter sections, such as connecting rods, are usually finished at the lower temperature, while heavy sections, such as driving axles, are finished near the higher temperature mentioned.

Heat Treatment of Locomotive Forgings—After the forging operation is completed, the forgings should be allowed to cool to below the critical range under suitable conditions to prevent injury by too rapid cooling. To remove forging stresses and to refine the grain, an appropriate heat treatment should then follow.

*This article was prepared by the Subcommittee on the Heat Treatment of Locomotive Forgings. The membership of the subcommittee was as follows: M. A. Herzog, Chairman; J. H. Higgins, J. A. Succop and P. E. McKinney.

The heat treatment may consist of annealing, but it is the usual practice for high duty locomotive forgings in which better physical properties are required, to receive a treatment consisting of normalizing followed by tempering.

When forgings are to be bored or rough machined, preliminary to normalizing and tempering, they may be annealed to improve their machinability.

Annealing—The purpose of annealing a forging is to refine the grain structure, increase the ductility, or soften it for ease of machining. Annealing consists of heating to a temperature above the critical range, holding a sufficient length of time at that temperature, and then cooling in the furnace or under other suitable conditions to secure uniform retarded cooling.

Normalizing and Tempering Locomotive Forgings—The purpose of normalizing locomotive forgings is to refine the grain structure and to secure the highest combination of physical properties without resorting to quenching in a liquid medium. The temperature must be held a sufficient time to permit complete grain refinement in the forgings.

Normalizing may consist of a single heating to a temperature above the critical range followed by cooling in the air, or of a sequence of such heatings and coolings. If a sequence of heatings and coolings is used, the temperature may vary. A decrease in temperature is usually made for each successive heating, but the temperature for each heating should be above the critical range. Normalizing should be followed by tempering.

To eliminate the lack of uniformity in the grain structure of forgings, resulting from variations in reduction and finishing temperatures, and to produce a homogeneous grain structure throughout the forgings which will respond uniformly to the usual normalizing temperature, it is often desirable, particularly with large forgings, to first normalize the forgings at a temperature much above the upper critical limit (approximately 1750-1850°F.).

Tempering—The purpose of tempering is to remove strains set up in the forgings during the cooling from the normalizing temperature. The ductility of the forgings is increased by tempering, while the tensile strength may be slightly reduced. Tempering is not intended to change the grain size, therefore the temperature is below the critical range. After tempering, the forgings may be cooled in the air, slowly with the furnace, or under other conditions to secure uniform retarded cooling. The forgings should be held at temperature a sufficient time to insure complete penetration of the heat.

In annealing, normalizing, and tempering, the choice of temperatures used, the number of normalizing treatments, the length of time that the forgings are held at temperature, the method of cooling in annealing and tempering, all must be determined by experience, taking into account the type of steel, the size and character of the forgings, and the condition of the furnace used.

Temperatures and Times of Heating—In view of the large number of variable conditions involved, it is impossible to lay down exact rules of procedure for annealing, normalizing, and tempering, with stated temperatures and times of heating which will be applicable under all conditions. The following sections give general information regarding temperatures and times of heating which may be expected to give satisfactory results under favorable conditions. The information is given only as a guide and not as standard practice for all cases. Experience based on the actual conditions involved will sometimes show that better results are obtained by the use of other temperatures.

Table I.
Heating and Holding Time for Forgings

Thickness of Largest Section of Forging	Approx. Time of Heating, Hr.	Approx. Time of Holding, Hr.
		Medium Charge
Up to and including 5 in.....	8	{ Carbon steel, $\frac{1}{2}$ hr. per in. of dia. or max. thickness. Alloy steel, $\frac{3}{4}$ hr. per in. of dia. or max. thickness.
Over 5 in. and including 8 in.....	8	
Over 8 in. and including 10 in.....	10	
Over 10 in. and including 12 in.....	12	

The rate at which forgings are heated to the normalizing and tempering temperatures must not be too rapid or the forgings may be injured. The proper rate will depend to a considerable extent on the design of the furnace. In general, the time allowed for each inch of diameter or thickness of the forging should be 45 minutes for raising to the normalizing temperature and 30 minutes for raising to the tempering temperature.

After the temperatures desired for normalizing have been reached, the forgings should be held at these temperatures a sufficient time to permit the desired changes in structure to be completed. A holding time of $\frac{1}{2}$ hr. for C and $\frac{1}{2}$ hr. for alloy steels per in. of dia. or max. thickness will usually be found satisfactory.

Table I gives, for general guidance, the time for heating and holding a medium furnace charge of forgings.

Normalizing and Tempering Temperatures—Table II gives, for general guidance, temperatures which may be used in normalizing and tempering forgings of the various compositions as indicated. The figures are based on a single normalizing treatment with slow cooling in the furnace from the tempering temperature. As previously stated, the temperatures may require modification to meet individual requirements.

Table II
Normalizing and Tempering Locomotive Forgings

C	Mn	Si	V	Ni	Normalizing Temp., °F.	Tempering Temp., °F.	Approx. Ten. Str., Psi.
0.40-0.45	0.50-0.85	0.18-0.30	1500-1550	1000-1100	80,000
0.45-0.50	0.50-0.85	0.18-0.30	1475-1525	1100-1250	80,000
0.50-0.55	0.50-0.85	0.18-0.30	1450-1500	1200-1350	80,000
0.45-0.50	0.70-0.95	0.18-0.30	0.15-0.25	1575-1650	1050-1250	95,000
0.50-0.55	0.70-0.95	0.18-0.30	0.15-0.25	1575-1650	1050-1250	95,000
0.35-0.40	0.50-0.80	0.18-0.35	3.25-3.75	1425-1450	1000-1150	90,000
0.40-0.45	0.50-0.80	0.18-0.35	3.25-3.75	1400-1425	1050-1200	90,000
0.20-0.30	0.80-1.00	0.18-0.35	2.50-3.00	1425-1475	1000-1200	80,000

Annealing temperatures will usually be lower than the normalizing temperatures. The difference is approximately 50°F. lower for annealing the plain carbon steels, 25°F. lower for the nickel steels, and 100°F. lower for the vanadium steels.

Appendix—The following information was taken from specifications of the Association of American Railroads, covering the chemical and mechanical properties of railroad forging of carbon and alloy steels:

A. A. R. Specification M-102-34—Chemical Composition—The steel for grade 3 shall conform to the following requirements as to chemical composition, given in per cent: C, 0.40-0.55; Mn, 0.50-0.90; P, 0.045, max.; and S, 0.05, max.

Tension Tests—Grade 3 forgings shall conform to the following minimum requirements as to tensile properties:

Unannealed Condition

Size, Outside Dia. or Over-all Thickness	Tensile Strength, Psi.	Yield Point, Psi.	Elongation in 2 in., %		Reduction of Area, %	
			Inverse Ratio	Not Under	Inverse Ratio	Not Under
Not over 8 in.	75,000	0.5 ten. str.	1,600,000 ÷ ten. str.	18	2,200,000 ÷ ten. str.	24
Over 8-12 in., incl..	75,000	0.5 ten. str.	1,500,000 ÷ ten. str.	17	2,000,000 ÷ ten. str.	22

Annealed Condition

Size, Outside Dia. or Over-all Thickness	Tensile Strength, Psi.	Yield Point, Psi.	Elongation in 2 in., %		Reduction of Area, %	
			Inverse Ratio	Not Under	Inverse Ratio	Not Under
Not over 8 in.	80,000	0.5 ten. str.	1,800,000 ÷ ten. str.	20	2,800,000 ÷ ten. str.	32
Over 8-12 in., incl..	80,000	0.5 ten. str.	1,725,000 ÷ ten. str.	19	2,640,000 ÷ ten. str.	30
Over 12-20 in., incl.	80,000	0.5 ten. str.	1,650,000 ÷ ten. str.	18	2,400,000 ÷ ten. str.	28

A. A. R. Specification M-104-34—Chemical Composition—(a) The chemical composition of the forgings shall conform to the following:

Class	A	B	C
Carbon, %	0.40-0.55	0.40-0.55	0.20-0.30
Manganese, %	0.60-0.90	0.65-0.95	0.65-0.95
Phosphorus, % max.	0.045	0.045	0.045
Sulphur, % max.	0.05	0.05	0.05
Silicon, %	0.15 min.	0.15 min.	0.15-0.35
Vanadium, % min.	0.15
Nickel, %	2.50-3.00

(b) The steel shall not show residual alloying metal impurities in excess of the following limits:

Chromium, %	0.15	0.15	0.15
Nickel, %	0.25	0.25

Tension Tests—(a) The forgings shall conform to the following minimum requirements for tensile properties:

Class A

Size, Outside Dia. or Over- all Thickness	Tensile Strength, Psi.	Yield Point, Psi.	Elongation in 2 in., %		Reduction of Area, %	
			Inverse Ratio	Not Under	Inverse Ratio	Not Under
Not over 8 in. (4 in. max. wall)	88,000	50,000	2,300,000 ÷ ten. str.	25	3,650,000 ÷ ten. str.	40
Over 8-12 in. (6 in. max. wall)	86,000	48,000	2,100,000 ÷ ten. str.	24	3,320,000 ÷ ten. str.	38
Over 12-20 in. (10 in. max. wall)	84,000	46,000	2,000,000 ÷ ten. str.	23	3,100,000 ÷ ten. str.	36

Class B

5-9 in.	90,000	60,000	22	44
9-13 in.	90,000	58,000	21	42

Class C

Under 8 in.	80,000	55,000	28	60
8 in. and over.	80,000	55,000	28	55

Composition and Heat Treatment of Spline Shafts*

General—This article covers the processes to be followed for the heat treatment of spline shafts. A spline shaft is so constructed that it interlocks, either rigidly or sliding, with a part or parts, such as gears. Thus a spline shaft may have one or more keyways, or one or more keys, but it is not customary to have both keys and keyways on the same shaft. Spline shafts are used in two general classes of work, represented by automotive parts and machine tool parts. Short shafts are widely used in automotive parts, whereas long spline shafts are more common in machine tools. No arbitrary dimensions are set in distinguishing between long and short shafts, but in general, shafts not over 12 in. in length or $1\frac{1}{2}$ in. in diameter may be called "short" spline shafts. It should be understood that the selection of a steel for a spline shaft is not limited to the steels discussed, for steels other than those listed have been successfully used. However, it is believed that the lists given include most of those that have been found satisfactory.

Design—As spline shafts in operation are subjected to alternating stresses, their endurance limit of resistance to fatigue is of importance. The shaft should be designed to eliminate unnecessary necks and sharp corners where stresses might be concentrated. Fillets and machined grooves in splines should always be gradually rounded up.

Stiffness is one of the necessary properties of some types of spline shafts, particularly long shafts. Shafts should be designed of sufficient section so that harmful deflection will not occur under the applied load. Where the design is incorrect, the shaft may twist or bend, thus causing undesirable effects due to alternating stress, vibration, and the like, which will be felt in the gears or other moving parts as well as in the shaft. Heat treatment may raise the elastic limit of the steel, but it will not change the modulus of elasticity. For this reason, heat treated shafts may not be any stiffer than untreated shafts, when operating below the elastic limit.

Distortion—Distortion is the trouble most commonly encountered in the heat treatment of spline shafts. To avoid distortion care must be exercised in all operations. The steel must be carefully selected and inspected. If much machining is performed on the shafts, the machining stresses should be relieved by normalizing or annealing before subjecting the shafts to the final heat treatments.

The carburizing and heat treating operations should all be carried out with extreme care. It may be necessary with some carburized spline shafts to omit the double treatment and to carburize at a lower temperature to avoid distortion.

There are many spline shafts made of bar stock of either black hot rolled finish, or bright cold drawn finish. In either case this material is more liable to distortion than a properly normalized forging; and therefore when minimum straightening is essential, spline shafts made of bar stock should be normalized in the same way as forgings unless the straightening operation is considered absolutely necessary on the finished shaft. If hot rolled or cold drawn bar stock is used, it is essential that $\frac{1}{4}$ - $\frac{1}{2}$ in. should first be machined from the outer surface to insure a clean surface for hardening.

Keyways in a spline shaft may cause distortion in quenching. Unless designed with ample section, a shaft with a keyway has less stiffness than one carrying keys integral with the shaft. To minimize distortion in quenching, it is advantageous to have more than one integral key. These keys are equally spaced about the shaft to facilitate equal cooling and to balance the section.

Chemical Composition of Spline Shaft Steels—Three types of steel are commonly used for spline shafts. These are the carburizing, water hardening, and oil hardening types and include the following steels:

Carburizing Steels—1020, 2315, 2320, 2512, 2520, 3115, 3120, 3312, 3415, 4615, 4620, 4815, and Manganese A.¹

Water Hardening Steels—1045, 1335, 2320, 4130.

*This article was prepared by the Subcommittee on Spline Shafts. The membership of the subcommittee was as follows: G. M. Enos, Chairman, H. Stanley Binns, A. H. d'Arcambal, L. A. Danse, H. B. Knowlton, and E. O. Mann.

¹C 0.15-0.25; Mn 0.90-1.10; P 0.04-0.06; S 0.04-0.06; Cr 0.15-0.25.

Oil Hardening Steels—1335,^a 1340, 2345, 3140, 3250, 3450, 4140, 6150, and Manganese B.^a

Selection of Steels for Spline Shafts—Spline shafts which are not to be highly stressed can be satisfactorily made from steel 1020 or 1315. To make the shaft sufficiently stiff, it is sometimes designed large enough so that these steels may be used instead of alloy steels.

For small shafts which are to be carburized, steels 3115, 2512, 3312, 2315, 4615 and 4815 are satisfactory. If the diameter is over 1½ in., the carbon content can be increased slightly without encountering brittleness on quenching. For example, for large shafts steels 3415, 3120, 2320, 2520, 4620, or 4815 are satisfactory.

While the water hardening steels can be used, it should be pointed out that water quenching may result in cracking, particularly if the design is such that the shaft will be susceptible to cracking. Steel 1045, although used for spline shafts, is not entirely satisfactory. It does not always respond uniformly to heat treatment, whereas 1335 does.

The steels designated as Manganese A, B, and 1335 are representative of the manganese structural steels. Steels of this general type are used successfully in spline shafts. They machine freely, have good physical properties and harden without difficulty.

In addition to these manganese steels, steels 1340 and 1345 are used to some extent for spline shafts. These steels contain carbon 0.35-0.45, and 0.40-0.50% respectively with 1.60-1.90% manganese. They do not machine so readily as the manganese steels listed, but have excellent physical properties and are of the oil quenching type.

The oil hardening steels listed are in general quite satisfactory.

Normalizing and Annealing of Carburizing Steels—To normalize the carburizing steels, heat thoroughly to a temperature between 1650° and 1825°F. For best results in machining, the temperature should be at least 50° above the carburizing temperature. Holding too long at elevated temperatures has the disadvantage of causing excessive scaling, if the furnace atmosphere is not properly controlled. Cool slowly, to give the desired machining qualities.

Careful annealing of helical spline shafts is essential, so as to minimize the movement of the helical angle or lead in subsequent heat treatment.

Carburizing—Carburize to a depth to suit individual requirements. The methods of carburizing as given in this Handbook may be followed. The conventional carburizing process (packing the material in a carburizing compound in a box) is satisfactory. Long and short shafts should stand vertically in the box, but uniform heating is essential, which in some furnaces may require horizontal heating at a sacrifice of straightness. The carburizing temperatures and the heat treatments for carburized spline shafts are given in Table I.

Quenching Treatments for Carburized Spline Shafts—There are several possible quenching treatments which may be given. They are as follows: (1) A direct quench from the box, and (2) a single, or (3) double quench after cooling in the box. The factors which govern a choice of methods are: (1) Shock resistance desired, (2) grain growth characteristics of the steel, (3) distortion. Thus in some plants for certain steels, experience has shown that suitable impact values and minimum distortion were obtained on direct quenching from the box. It is common practice, however, to use the single quench, namely, cool in the box after carburizing, reheat to the temperature given in Table I for the single heat treatment, followed by quenching. With the single quenching treatment it is advisable to use lower carburizing temperatures, and if the structure is coarse after carburizing, it is advisable to use the higher reheating temperature (single treatment) as given in Table I. It is, of course, desirable to hold distortion to a minimum. By selecting steels which do not coarsen at the carburizing temperature used, distortion is held to a minimum by direct quenching from the box, or by a single reheat after cooling in the box.

A double quench as given in Table I will give case and core refinement and resistance to shock and impact, without exercising great care in the control of grain size. It is open to the objection that more distortion may occur.

^aC 0.35-0.40; Mn 1.60-1.90; P 0.040; S 0.050.

^aC 0.45-0.55; Mn 0.90-1.10; P 0.045; S 0.050; Cr 0.45-0.60.

4815	1600-1700	box	1600	oil	1375	oil	1375-1425	oil	275-400

¹Carburizing at the lower temperature causes less distortion, while at the higher temperature more rapid penetration is secured. The tendency is to make 1650°F., the minimum carburizing temperature.

²Many find it desirable to quench from 1450-1550°F.

³There is considerable difference of opinion as to the tempering temperatures that should be used for various steels. For some steels a lower tempering temperature, but not less than 275°F., may be desirable.

For hardening it may be suggested that the spline shafts be hung vertically from eyebolts in the furnace, and also quenched vertically from the same eyebolts on both single and double quenched shafts. Spline shafts are always out in relation to the keyway. Shafts can be quenched in a fixture or on a machine on the final heat, so that they will come straight enough to clean up on grinding when an ample amount of grinding stock is allowed. By using this method, the straightening operation may be unnecessary in many cases.

Spline shafts can also be heated in a horizontal position in a continuous furnace provided the supports are properly spaced. The shafts come out fairly straight although they usually require some straightening.

Tempering Carburized Spline Shafts—In tempering, the highest temperature should be used that will give the desired hardness.

Normalizing and Annealing Water Hardening Steels—To normalize or anneal the water hardening steels for spline shafts, heat openly, exposing maximum surface area, to a temperature of 1600-1700°F. for steel 1045 and to 1650-1750°F. for steels 2320 and 4130. For this treatment the steels should be held at temperature only long enough to insure complete penetration of heat. From these temperatures the steels may be cooled in the air or cooled at a rate to produce the desired machining qualities.

Table II
Hardening and Tempering of Water Hardening Spline Shafts

Steels	Quenching Temp., °F.	Quench in	Tempering Temp., °F.
1045	1475-1525	Water	700-1200
1335	1475-1525	Water	700-1200
2320	1600-1650	Water	700-1200
4130	1475-1525	Water	700-1200

Hardening and Tempering Water Hardening Steels—The quenching and tempering temperatures for the water hardening steels are given in Table II. Before quenching in water, it may be advisable to first quench these steels for a few seconds in oil. The shafts should always be removed from the water before they become cold.

Normalizing and Annealing Oil Hardening Steels—After forging, these steels should be normalized or annealed. The following is a form of normalizing suitable for steels 1335, 2345, 3250, 3450, 6150, and Manganese B, and produces good machining qualities.

Heat the steels slowly, while exposing the maximum surface area, to a temperature of 1650-1700°F. Hold at heat only long enough to insure thorough and uniform heating. Cool rapidly by opening furnace doors to 1280°F. Cool slowly from 1280-1000°F. over a period of from 6-10 hr. for good machining.

Steel 3140 may be normalized by heating slowly and uniformly, while exposing maximum surface area, to a temperature of 1575-1625°F. and cooling from this temperature slowly in air.

Steel 4140 may be normalized by heating slowly and uniformly to a temperature of 1650-1700°F. and cooling slowly in air.

Hardening and Tempering Oil Hardening Steels—The quenching and tempering temperatures for the spline shafts made from oil hardening steels are given in Table III.

Table III
Hardening and Tempering Oil Hardening Spline Shafts

Steels	Quenching Temp. ¹ , °F.	Quench in	Tempering Temp. ² , °F.	Approximate Brinell Hardness
1335	1500-1525	Oil or water	900-1000	255-217
1340	1500-1525	Oil	900-1000	321-255
3145	1425-1450	Oil	900-1050	351-300
	1525-1550	Oil	650- 750	430-375
3250	1475-1500	Oil	475- 750	529-430
3450	1475-1500	Oil	750- 850	460-387
4135	1525-1550	Oil	550- 650	400-387
6150	1575-1600	Oil	700- 800	444-351
Manganese B	1475-1525	Oil	900-1000	400-321

¹Most oil hardening spline shafts are quenched from 1450-1550°F. Many of them are hardened in cyanide.

²Tempering temperatures here suggested may be changed to suit conditions. Some find 400-450°F. satisfactory.

Steel 3145 may be hardened in two different ways, as indicated in Table III. The method giving a high tempering temperature consists in hardening the shaft vertically, with the spline or keyway not cut, and leaving ample stock for grinding. The keyway is then milled after the heat treatment. If the steel has been properly normalized and carefully handled, straightening is rarely needed, but it can be done at the tempering heat if necessary. After tempering, the shafts are rough ground to 0.010 in. large, then the spline is milled, and the spline shafts are finish ground.

This same sequence of operations may be followed for any of the steels listed in Table III. The tempering temperature would then necessarily be higher than indicated in the table in order to make machining possible. By using this treatment on steels 3250 and 3450, more ductility may be obtained than is possible with steel 3145.

Spline shafts may be difficult to straighten after quenching. For example, shafts made with ample grinding stock from steel 3450 may be designed to have either two splines equally spaced or three integral keys, which eliminates the unbalanced distortion. If steels 3250 and 3450 have to be straightened, it is done at the tempering temperature or before tempering.

When steel 3145 is tempered at the lower temperature, the same method as outlined for steel 3450 is used. However, it may be possible to jig or machine quench this steel with a single spline, so that it will come within a reasonable grinding allowance.

Steel 6150 distorts in heat treating more than the steels previously discussed. However, it withstands abuse, and has high strength and fatigue resistance values.

As it has been suggested that straightening may be easier if the grain size is controlled, a 5-7 grain size is recommended. The use of a vertical retort furnace with controlled atmosphere minimizes straightening and grinding.

Composition and Heat Treatment of Small Flat Springs*

Cold Formed From Plates Less Than $\frac{1}{4}$ In. Thickness

General—This article covers the process to be followed in the heat treatment of small flat plates designed for springs used for miscellaneous purposes. The practice includes only springs made from plates less than $\frac{1}{4}$ in. in thickness.

Table I
Chemical Composition of Flat Bars Used for Cold Formed Small Springs

Name of Steel	C	Mn	P Max.	S Max.	Cr	V Min.
Cold rolled	0.45-0.70	0.80-1.20	0.04	0.045
Oil tempered	0.55-0.70	0.90-1.20	0.04	0.045
Annealed	0.55-0.70	0.90-1.20	0.04	0.045
Oil tempered	0.60-0.70	0.30-0.60	0.04	0.045
Oil tempered	0.80-0.90	0.30-0.60	0.04	0.045
Annealed	0.80-0.90	0.30-0.60	0.04	0.045
Cold rolled	0.90-1.05	0.30-0.50	0.04	0.045
Cold rolled, Cr-V	0.45-0.55	0.60-0.80	0.04	0.040	0.80-1.10	0.15
Annealed, Cr-V	0.45-0.55	0.60-0.80	0.04	0.040	0.80-1.10	0.15
Oil tempered, Cr-V	0.45-0.55	0.60-0.80	0.04	0.040	0.80-1.10	0.15

Imperfections—The flat bars should be free from surface cracks, hair line seams, surface decarburization,¹ slag inclusions, die scratches, localized segregations, slivers, and cuts. These defects cause premature failure as they are a source of starting points for fatigue.

Hardness—The flat bars as received from the manufacturer should have even hardness in order to obtain uniform results in coiling and forming.

Chemical Composition—The chemical compositions of the steels generally used for cold formed small flat springs of less than $\frac{1}{4}$ in. thickness are given in Table I.

Table II
Heat Treatment of Cold Formed Small Flat Springs

Steel as Listed in Table I	Carbon Range	Quenching Temp., °F.	Quenching Media	Tempering Temp., °F.	Approximate Rockwell "C" Hardness
Cold rolled	0.45-0.70	Cold rolled	...	450-600 ¹	35-40
Oil tempered	0.55-0.70	Pretempered	...	450-600 ¹	35-40
Annealed	0.55-0.70	1450-1525	Oil	700-850	35-40
Oil tempered	0.60-0.70	Pretempered	...	450-600 ¹	35-40
Oil tempered	0.80-0.90	Pretempered	...	450-600 ¹	35-40
Annealed	0.80-0.90	1425-1500	Oil	800-850	35-40
Cold rolled	0.90-1.05	Cold rolled	...	325-375 ¹	35-40
Cold rolled, Cr-V	0.45-0.55	Cold rolled	...	450-650 ¹	35-40
Annealed, Cr-V	0.45-0.55	1575-1625	Oil	850-950	35-40
Oil tempered, Cr-V	0.45-0.55	Pretempered	...	450-650 ¹	35-40

¹Oil tempered and cold rolled flat springs are usually given a short tempering to relieve forming strain.

Heating and Quenching—To prevent excessive scaling the springs made from annealed flat bars should be heated uniformly in a suitable furnace or liquid bath to the quenching temperatures given in Table II. The springs are then quenched rapidly in circulating oil which is maintained at a temperature of 100-140°F.

Tempering—The springs should be heated in a suitable tempering medium to the temperature given in Table II. They should be held at this temperature for a sufficient length of time to permit complete penetration of the heat. The method of cooling after tempering is not important.

*This article was prepared by the Subcommittee on the Heat Treatment of Springs. The membership of the subcommittee was as follows: W. H. Phillips, Chairman; Henry Chandler, H. W. Faus, DuRay Smith, and A. K. Strandberg.

¹Surface decarburization should be maintained at a minimum because recent investigation has demonstrated that decarburization as small as three thousandths of an inch will materially reduce the endurance value of spring steels.

Composition and Heat Treatment of Large Flat Springs*

Hot Formed from Plates $\frac{1}{4}$ in. in Thickness or Over

General—This article covers the process to be followed for the heat treatment of hot formed flat springs both plain carbon and alloy steel. The article includes only springs made from plates of $\frac{1}{4}$ in. in thickness or over and of the type generally used for railway equipment, but also used extensively for miscellaneous applications.

Imperfections—The bars should be free from surface cracks, rolling seams, pipes, surface decarburization,¹ inclusions, and carbide segregation. These imperfections have a tendency to cause early failure of a spring as they are a source of starting points for fatigue. Carbide segregation and inclusions also cause quenching cracks.

Hardness—The steel as received from the manufacturers should be soft enough to permit the simple cold working operations (shearing, punching, trimming, and bending) without cracking.

Chemical Composition—The chemical compositions of the steels generally used for hot formed flat springs of $\frac{1}{4}$ in. thickness or over are given in Table I.

Table I
Approximate Chemical Composition of Steels Used for Hot Formed Large Flat Springs

Steels	C	Mn	P Max.	S Max.	Si	Cr	V
Low C ¹	0.70-0.80	0.50-0.80	0.04	0.04
C	0.90-1.05	0.25-0.50	0.04	0.05
Si-C	0.90-1.05	0.25-0.50	0.04	0.05	0.25-0.50
Si-C-V	0.88-0.98	0.45-0.65	0.045	0.045	0.50-0.75	0.15
Cr-V	0.45-0.55	0.70-0.90	0.040	0.040	1.00-1.20	0.15
Si-Mn	0.50-0.60	0.60-0.80	0.045	0.045	1.80-2.20

¹Used for flat springs less than $\frac{1}{4}$ in. in thickness.

Heating for Slotting, Nibbing, Spear-Pointing, and Tapering—For these operations the plates should be heated in a suitable furnace to a temperature not in excess of 1800°F.

Heating for Forming—For forming, the plates should be heated uniformly in a furnace to the lowest temperature at which the steel will work satisfactorily, and in no case should this temperature exceed 1750°F. Generally, the normalizing temperatures given in Table II will be found very satisfactory for the forming temperatures. After forming the springs should be cooled in air until they become distinctly black.

Annealing—When annealing is necessary for machining, to relieve machining strains, cold working strains, or strains from local heating, the steel may be heated to 1250-1325°F. The rate of cooling will vary with the requirements.

Table II
Heat Treatments of Hot Formed Large Flat Springs

Steels As Listed in Table I	Normalizing ¹ Temp., °F.	Quenching Temp., °F.	Quenching Media	Tempering Temp., °F.	Approximate Brinell Hardness
Low C	1450-1475	Oil	700- 850	352-415
C	1575-1600	1500-1550	Oil	850-1050	352-415
Si-C	1600-1625	1525-1575	Oil	850-1050	352-415
Si-C-V	1625-1650	1600-1625	Oil	750-1050	363-429
Cr-V	1600-1625	1600-1625	Oil	850-1050	363-429
Si-Mn	1600-1625	1575-1600	Oil	850-1050	363-429

¹These normalizing temperatures are also often used for the forming temperatures.

*This article was prepared by the Subcommittee on the Heat Treatment of Springs. The membership of the Subcommittee was as follows: W. H. Phillips, Chairman; Henry Chandler, H. W. Faus, DuRay Smith, and A. K. Strandberg.

²Surface decarburization should be maintained at a min. because recent investigation has demonstrated that decarburization as small as three thousandths of an in. will materially reduce the endurance value of spring steels.

Heating and Quenching—After the springs have been allowed to cool to a distinct black from the forming temperatures, they should be uniformly reheated in a suitable furnace to the quenching temperatures given in Table II. The heating time in minutes may be determined approximately by multiplying the thickness of the plate by 60.

After being held at temperature for a sufficient time to allow for complete penetration of heat, the springs are quenched in an ample volume of circulating oil which is maintained at a temperature of 100-140°F. The springs should be kept in the oil until they are cooled to a temperature of not more than 300°F. or until sufficiently cold to prevent the oil from flashing when they are removed from the oil.

Tempering—For tempering, the plates should be heated in a suitable tempering medium to the tempering temperatures given in Table II. They should be held at this temperature for a sufficient length of time to permit complete penetration of heat. The method of cooling after tempering is not important. After tempering in a salt bath, a hot water dip removes the salt film from the springs.

Composition and Heat Treatment of Small Helical Springs*

Cold Colled from Wire $\frac{1}{2}$ in. Diameter or Less

General—This article covers the process to be followed in the heat treatment of cold formed small helical springs designed and used for miscellaneous purposes. The practice includes only springs made from wire less than $\frac{1}{2}$ in. in diameter.

Imperfections—The wire should be free from surface cracks, hair line seams, surface decarburization,¹ slag inclusions, die scratches, localized segregations, slivers and cuts. These defects cause premature failure as they are a source of starting points for fatigue.

Hardness—The wire as received from the manufacturer should have even hardness in order to obtain uniform results in coiling and forming. All spring wire sizes of $\frac{1}{4}$ in. and less should be sufficiently ductile to wind on their own diameter as an arbor.

Wires Used in the Spring Industries

Cold Worked Wire (Music Wire)—Music wire is a cold worked wire supplied the spring manufacturers to be made into springs without any further heat treatment, except perhaps a short heating to relieve coiling or forming strains. This wire is of high carbon steel, usually made by the acid process, and its high tensile properties are obtained from its high carbon content and from many passes in the cold working dies or rolls. Its toughness is obtained from a process called patenting. This patenting process consists of passing the hot rolled material rapidly through a furnace at a temperature of about 1800°F. (the wire is at a much lower temperature) and then quenching into lead or air at a speed to produce sorbite, which will enable the steel to withstand severe reduction without developing brittleness. The wire is then cleaned and passed through drawing dies, during which time the coarse grains obtained by the heat treatment are elongated into fibres, producing a wire of great toughness, tensile strength, and particularly torsional strength. This wire is nearly always used in small sizes. Commercial sizes range from 0.004-0.135 in. diameter, and are of a bright surface finish.

Hard Drawn Wire—Hard drawn wire is another cold worked wire furnished the spring manufacturers to be made into springs without any further heat treatment, except perhaps a short tempering to relieve coiling or forming strain. This wire, like the music wire, has its tensile properties enhanced through cold working, but differs from the music wire in that it is simply "process annealed" between passes through the drawing dies instead of "patented." The process anneal consists of heating the wire considerably under the critical range to relieve the cold working strain but leaves the structure undisturbed. The steel in the hard drawn wire is of lower quality than music wire since it is usually made from lower grade material.

Hard drawn spring wire is made from stock with an analysis similar to "oil tempered wire," but it is usually drawn to a lower tensile strength and has a considerably lower yield point. With the same tensile strength, the elastic limit of hard drawn wire is less than for oil tempered wire of the same size.

Oil Tempered Wire—This wire is furnished the spring manufacturers in a heat treated condition, no further heat treatment being required after the wire has been made into springs, except perhaps a short heating to relieve coiling or forming strains. This wire, after having been alternately annealed and cold worked to finished size, is usually heat treated by a continuous process which consists of reeling the wire through shallow tanks of molten lead maintained at 1575-1625°F. The wire is then quenched either into a lead bath whose temperature is slightly above the melting point of lead; into oil which is at a temperature of about 140°F.; or into some other liquid. For tempering, the wire may be heated in an open furnace, in a tank of molten lead, in hot oil, or by bringing it in contact with hot sand or with plates or discs of iron or steel.

*This article was prepared by the Subcommittee on the Heat Treatment of Springs. The membership of the subcommittee was as follows: W. H. Phillips, Chairman; Henry Chandler, H. W. Faus, DuRay Smith, and A. K. Strandberg.

¹Surface decarburization should be maintained at a minimum because recent investigation has demonstrated that decarburization as small as three thousandths of an inch will materially reduce the endurance value of spring steels.

With uniform toughness or ductility, the tensile strength of oil tempered wire varies, being high for small and low for large sizes. This type of wire is heat treated to develop certain uniform qualities of toughness, tensile strength, reduction of area and Rockwell hardness. These properties indicate the ability of the wire to make the severe bends, without fracture required in forming springs.

Annealed Wire—This wire is supplied the spring manufacturers in an annealed condition, and used for springs which are to be hardened and tempered after the wire has been made into springs. After being alternately process annealed and cold worked to finished size this wire is annealed by heating to a temperature of about 1350-1400°F., a temperature which is slightly below the upper critical range of the wire, and which thus produces a partial or complete spheroidization of the carbide. The annealing is usually done in a muffle furnace, a tube furnace, or in lead. Since heat treatment is unsuitable on very fine gage wire because of surface damage and oxidation, tiny springs are made of cold drawn wire instead of being annealed.

Other Kinds of Wire—Other wire materials used for springs are monel metal, brass, phosphor bronze, and many other alloys containing nickel, chromium, manganese, vanadium, molybdenum, tungsten, and silicon, which may be drawn into wire with a reasonably high tensile strength and sufficient ductility for forming springs.

The purpose of various types of special alloys for springs is either to increase fatigue life, to increase resistance to corrosion, or to increase resistance to temperature. The difficulties of producing these alloys in the correct wire size and of sufficiently high strength, as well as the additional cost, limit their use for the manufacture of springs.

Certain grades of stainless steel in the finer sizes may be hard drawn to a tensile strength of at least 75% of that found in music wire and may at the same time retain excellent toughness and ductility for spring purposes.

Low Temperature Annealing—Hardening or tempering of spring wire should not be confused with the low temperature heat treatment after coiling, which is actually a low temperature anneal for the purpose of relieving coiling strains. This anneal may actually increase the elastic limit of the spring wire and increase its resistance to permanent deformation. Springs which will set as coiled may be deflected considerably more after a low temperature anneal without taking a permanent set.

Low temperature annealing for steel may range from 300-800°F., depending entirely upon the stock, the structure of the wire, and the results desired. Usually a temperature of 500°F. will give the maximum benefit.

Chemical Composition—The chemical compositions of steel wires generally used for cold coiled small helical springs made from ½ in. diameter wire or less are given in Table I.

Table I

Chemical Composition of Steel Wire Used for Cold Coiled Small Helical Springs

Name of Wire	C	Mn	P Max.	S Max.	Cr	V Min.
Hard drawn	0.45-0.70 ¹	0.80-1.20	0.04	0.045		
Oil tempered	0.55-0.70	0.90-1.20	0.04	0.045		
Annealed	0.55-0.70	0.90-1.20	0.04	0.045		
Oil tempered	0.60-0.70	0.30-0.60	0.04	0.045		
Oil tempered	0.80-0.90	0.30-0.60	0.04	0.045		
Annealed	0.80-0.90	0.30-0.60	0.04	0.045		
Music	0.80-0.95	0.30-0.50 ²	0.04	0.045		
Annealed	0.90-1.05	0.30-0.50	0.04	0.045		
Hard drawn, Cr-V	0.45-0.55	0.50-0.80	0.04	0.040	0.80-1.10	0.15
Annealed, Cr-V	0.45-0.55	0.50-0.80	0.04	0.040	0.80-1.10	0.15
Oil tempered, Cr-V	0.45-0.55	0.50-0.80	0.04	0.040	0.80-1.10	0.15

¹In small sizes the carbon is often lower.

²The manganese is often lower in some music wire.

Heating and Quenching—To prevent excessive scaling the springs made from annealed wire should be heated uniformly in a suitable furnace or liquid bath to the quenching temperatures given in Table II. The springs are then quenched rapidly in circulating oil which is maintained at a temperature of 100-140°F.

Table II
Heat Treatment of Cold Colled Small Helical Springs

Name of Wire As Listed in Table I	Carbon Range	Quenching Temp., °F.	Quenching Media	Tempering Temp., °F.	Approximate Rockwell "C" Hardness
Hard drawn	0.45-0.70 ¹	Cold worked	...	450-600 ²	40-45
Oil tempered	0.55-0.70	Pretempered	...	450-600 ²	40-45
Annealed	0.55-0.70	1450-1625	Oil	700-850	40-45
Oil tempered	0.60-0.70	Pretempered	...	450-600 ²	40-45
Oil tempered	0.80-0.90	Pretempered	...	450-600 ²	40-45
Annealed	0.80-0.90	1425-1500	Oil	800-850	40-45
Music	0.80-0.95	Cold worked	...	325-375 ³	See Footnote 3
Annealed	0.90-1.05	1450-1625	Oil	800-900	40-45
Hard drawn	0.45-0.55	Cold worked	...	450-650 ²	40-45
Annealed, Cr-V	0.45-0.55	1575-1625	Oil	850-950	40-45
Oil tempered, Cr-V	0.45-0.55	Pretempered	...	450-650 ²	40-45

¹Cushion springs may be 0.35-0.45 carbon.

²Oil tempered and hard drawn wire springs are usually given a short tempering to relieve coiling strain.

³Music wire is purchased according to tensile properties, not hardness.

Tempering—The springs should be heated in a suitable tempering medium to the temperature given in Table II. They should be held at this temperature for a sufficient length of time to permit complete penetration of the heat. The method of cooling after tempering is not important. After tempering in a salt bath, a hot water dip removes the salt film from the springs.

Composition and Heat Treatment of Large Helical Springs*

Hot Coiled From ½ In. Diameter Bars or Over

General—This article covers the process to be followed for the heat treatment of hot coiled helical springs of both plain carbon and alloy steel. The practice includes only large springs made from bar stock of ½ in. diameter or over and of the type generally used for railway equipment, but also used extensively for miscellaneous applications.

Imperfections—The bars should be free from surface cracks, rolling seams, pipes, surface decarburization,¹ inclusions and carbide segregation. These imperfections have a tendency to cause early failure of a spring as they are a source of starting points for fatigue. Carbide segregation and inclusions also cause quenching cracks.

Hardness—The steel as received from the manufacturers should be soft enough to permit the simple cold working operations (shearing, trimming, and bending) without cracking.

Chemical Composition—The chemical compositions of the steels generally used for hot coiled helical springs of ½ in. diameter or over are given in Table I.

Table I
Approximate Chemical Composition of Steels Used for Hot Coiled Large Helical Springs

Steels	C	Mn	P Max.	S Max.	Si	Cr	V
C	0.90-1.06	0.25-0.50	0.04	0.05
Si-C	0.90-1.06	0.25-0.50	0.04	0.05	0.25-0.50
C-Si-V	0.88-0.98	0.45-0.65	0.045	0.045	0.50-0.75	0.15
Cr-V ¹	0.45-0.55	0.70-0.90	0.04	0.04	0.90-1.15	0.15
Si-Mn ¹	0.50-0.60	0.60-0.90	0.045	0.045	1.80-2.20

¹These steels are used in special applications, as for example, in highly stressed helical springs.

Heating for Tapering—For tapering the bars should be heated in a suitable furnace to a temperature not in excess of 1800°F.

Heating for Coiling—For coiling the bars should be heated uniformly in a furnace to the lowest temperature at which the steel will work satisfactorily, and in no case should this temperature exceed 1750°F. Generally the normalizing temperatures given in Table II will be found very satisfactory for the coiling temperatures.

After coiling the springs should be cooled in air until they become distinctly black.

Annealing—When annealing is necessary for machining, to relieve machining strains, cold working strains, or strain from local heating, the steels may be heated to 1250-1325°F. The cooling rate will vary with the requirements.

Table II
Heat Treatment of Hot Coiled Large Helical Springs

Steels As Listed in Table I	Normalizing ¹ Temp., °F.	Quenching Temp., °F.	Quenching Media	Tempering Temp., °F.	Approximate Brinell Hardness
C	1575-1600	1500-1550	Oil	750-1050	352-415
Si-C	1575-1600	1525-1575	Oil	750-1050	352-415
C-Si-V	1625-1650	1600-1625	Oil	750-1050	363-429
Cr-V	1600-1625	1600-1625	Oil	850-1050	363-429
Si-Mn	1600-1625	1575-1600	Oil	850-1050	363-429

¹These temperatures are also often used for the coiling temperatures.

*This article was prepared by the Subcommittee on the Heat Treatment of Springs. The membership of the subcommittee was as follows: W. H. Phillips, Chairman; Henry Chandler, H. W. Faus, DuRay Smith, and A. K. Strandberg.

¹Surface decarburization should be maintained at a minimum because recent investigation has demonstrated that decarburization as small as three thousandths of an inch will materially reduce the endurance value of spring steels.

Heating and Quenching—After the springs have cooled to a distinct black from the coiling temperatures they should be uniformly reheated in a suitable furnace to the quenching temperatures given in Table II. The heating time in minutes may be approximately determined by multiplying the diameter of the steel in inches by 60.

After being held at temperature for a sufficient time to allow for complete penetration of heat, the springs are quenched in an ample volume of circulating oil which is maintained at a temperature of 100-140°F. The springs should be kept in the oil until they are sufficiently cold to prevent the oil from flashing when they are removed from the bath (about 300°F.).

Tempering—For tempering the springs should be heated in a suitable tempering medium to the temperatures given in Table II. They should be held at this temperature for a sufficient time to permit complete penetration of heat. The method of cooling after tempering is not important. After tempering in a salt bath, a hot water dip removes the salt film from the springs.

Heat Treatment of Tool Steels*

(General)

Purpose—Much of the general procedure for the heat treatment of one type of tool steel is applicable to others. These general instructions are to avoid repetitions in the articles on tool steels.

General—Often when correct temperatures are used, many hardening failures result from improper manipulation during heat treatment. The heat treatments given in the tool steel articles apply specifically to certain types of steels, the basic compositions of which are given. This does not imply that such steels are the only suitable ones. These articles are primarily for the purpose of recommending heat treatments.

For information on the relation of design to heat treatment, see page 214.

Forging—For information on the forging of tool steels see the tool steel articles in this section.

Normalizing—*Purpose*—Normalizing implies heating steel far enough above the critical range to carry all carbides into solution and when this is done, it is followed by air cooling; excess carbides may thus be broken up and a more uniform distribution obtained. This operation is more important on pieces that have been forged but should not be necessary on steel that has been annealed by the manufacturer unless subsequently forged.

Some steels should not be normalized. In general, steels that air harden are not normalized, such as high speed steel.

Rate of Heating—Heating tools for normalizing should be done in a manner similar to that described under heating for hardening. Correct soaking time is proportional to the size of the piece. Prolonged soaking will coarsen the grain, rendering subsequent refinement difficult.

Rate of Cooling—The material is cooled from the normalizing temperatures in still air.

Annealing—*Purpose*—Tool steel is annealed to soften it for machining, forming, and grain refinement.

Packing—Steel to be annealed should be placed in a tight container to keep out furnace gases. When pieces are small, they should be packed in cast iron chips, lime, mica, or other neutral material to prevent scaling, decarburization, and too rapid changes of temperature. Care must be taken to keep the steel from contact with the container, and to avoid the presence of scale.

Heating—Heat slowly and uniformly to the temperature desired (see specific tool steel articles in this Handbook).

Holding at Heat—Hold at the annealing temperature long enough for complete penetration of heat, and readjustment of grain. The time will increase with the weight of the charge and the alloy content of the steel, generally 1-4 hr. will be sufficient.

Cooling—Cool slowly, preferably in the furnace, or in mica or other good heat insulating material. In general, the slower the cooling, particularly through the critical range, the softer the steel. As the alloy content of the steel increases the slower the steel must be cooled. The maximum cooling rate of 50°F. per hr. down to 1000°F. is suggested.

Strain Relieving Anneal—This process, sometimes called subcritical annealing, is useful in removing residual strains induced by heavy machine work or other cold working. As indicated, it is usually carried out at temperatures below the critical range (1000-1200°F.). In many cases it is safely done in the open fire but for some tools packing is necessary to prevent scaling and decarburization. Air cooling may be safely used. This treatment often aids in minimizing warpage as well as breakage during hardening.

This practice is usually applied after machining and before hardening but it is often useful to rough machine, then strain relieve anneal before finish machining.

Heating for Hardening—*Rate of Heating*—The rate of heating for alloy tool steels should be proportionately slower than for plain carbon steels as the alloying content increases. In general, the slower and more uniform the heating, the less the warping or change in size or shape, provided other factors are unchanged.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman; A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, F. J. McCarthy, F. F. McIntosh, J. H. McCadle, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Attention is called to the fact that heating for hardening is most rapid in molten baths, somewhat slower in open or semimuffle fuel fired furnaces, and the slowest in electric or complete muffle type furnaces.

Cold tools should be charged at comparatively low furnace temperature (below 1000°F.). Sudden changes in temperature should be avoided, except where steels such as high speed are changed from preheating furnaces to high heating furnaces to obtain rapid heating. It is especially important to avoid sudden changes when reheating hardened steel, to prevent breakage.

The steel should be placed in the furnace so as to expose the maximum surface. It is often advisable to place supports under the tool to raise it from the furnace bottom, thus allowing better heat circulation. An intricate tool should be supported in such a manner as to avoid warping.

Large Sizes—A range of temperature is usually given in recommendations for hardening heats. This does not imply that satisfactory results can be obtained on any tool if held anywhere within that range. Generally the larger pieces are heated to the high side of the range while small pieces are heated to the low side.

Uniform Heating of Tools—Cylindrical tools or intricate parts that have a tendency to heat nonuniformly should be occasionally rotated.

Holding at Heat—Care should be taken to hold the tool at temperature long enough to insure uniform heating throughout the section of the piece. Usually, steel of higher alloy contents will require more time, as noted in specific tool steel articles. This gives a better solution of the carbides but excessive time at temperature may cause some grain growth and surface decarburization, particularly at temperatures well above the critical range.

For the time of holding high speed steel at quenching heat, see the tool steel article covering this steel.

Furnace Atmosphere—Proper control of furnace atmosphere is important and varies somewhat with the type of steel and the temperature used. For certain types of steels which show a tendency to produce a soft skin on the surface such as the oil hardening manganese tool steels, a slightly oxidizing atmosphere will overcome this condition. On the other hand, the best results for hardening high speed and high carbon, high chromium steels are obtained in an atmosphere with high CO and minimum CO₂. In either case, direct impingement on the steel of flames or gases of combustion should be avoided.

Effect of Scale—If tool steel is heated above a low red heat while in contact with scale, even though in a neutral or reducing atmosphere, it will be decarburized. Therefore, care should be taken to keep steel, furnace hearth, and containers as free from scale as possible.

Thermocouples—The thermocouple should be so placed that the flames do not strike it and so located as to indicate as nearly as possible the temperature of the tool. It is generally better to insert the thermocouple through the end or side of the furnace rather than through the top. Pyrometers should be frequently checked. For specific instructions see the article in this Handbook on Pyrometry.

Cooling—Quenching Medium—The quenching medium should vary with the kind of steel treated as well as the speed of cooling necessary for various types of tools. Sufficient volume of coolant should be provided to maintain the quenching medium at proper temperature for uniform results. The use of air as a means of agitation and cooling for liquid baths is not recommended.

Brine—Tools quenched in brine will more readily throw their scale, producing a cleaner surface of more uniform hardness. Brine is a more uniform quench than water when used in still or mildly agitated baths. On work of considerable mass or where definite flow directions are desired, sprays or geysers are necessary. Brine should be maintained at a fairly constant temperature. A range of 60-80°F. is suggested.

Water—Water should be held at a fairly constant temperature, usually between 50-70°F. Fresh tap water is often aerated and may produce soft spots, so that water which has been previously boiled, or has been used frequently, is recommended. When water is used as a quench it should be used in the form of a stream or spray designed to suit the tool to be quenched. The purpose is to circulate the water continuously against the surface to be hardened. This helps to sweep off scale and steam bubbles and results in more uniform hardening. Only small tools should be quenched in still water.

Oils—Oils generally give best results when used between the temperatures of 100-150°F. Avoid quenching in cold oil of not the proper fluidity. Some oils crack or otherwise deteriorate faster than others; consequently, should be reconditioned

as found necessary. Oil baths should be frequently checked for the presence of water. When quenching tools from a cyanide or salt bath, a straight mineral oil should be used to avoid decomposition of the oil.

Air—Certain types of tool steels require air cooling. Air cooling may be applied in three ways: (1) Air blast, which is the discharge from a high pressure line; (2) fan air, which is the current of air discharged from a fan; and (3) still air, which is atmospheric air undisturbed by artificial circulation. When using any one of the three methods the tool should be held or supported so as to allow uniform cooling, as nearly as possible. Caution should be observed in using air blast to apply it through a properly designed device and care taken to avoid the presence of water in the blast.

Special Quenching Media—Unusual conditions often require special quenching media, such as a solution of 5-10% sodium hydroxide in water which has a tendency to overcome soft spots and nonuniform hardening in carbon tool steels. A mixture of water and glycerine in any proportion will produce a rate of cooling intermediate between oil and water. For oil hardening steels the glycerine content is comparatively high (60-90% glycerine) whereas for water hardening steels the glycerine content is low (10-40% glycerine). Mercury can be used to obtain local hardening.

Quenching—Tools should be quenched in such a manner that warping is at a minimum. When immersing tools avoid the formation of gas pockets by vigorous agitation or by jets. It is important that the cooling medium come in contact with all parts of the work to be hardened. Usually tools should not be removed from the quenching bath until they are below 200°F. or to the point where water boils on them, neither should they be allowed to go cold in the quench. A good time to remove the tools is when all of the surface is approximately 125-150°F. Then, if any mass is involved, hold at this temperature until the tools become uniform in temperature throughout. This may be accomplished by placing in an oil bath for the required length of time. The tools are then ready for tempering and may be transferred to the tempering furnace. For specific instructions see the articles on tool steels in this Handbook.

Tempering—Strains—Tools, after removal from the quenching bath and before tempering, are always in a highly and nonuniformly strained condition and danger of cracking is most pronounced. Tools should not become cold before tempering.

Uniform Tempering—Satisfactory tempering results are obtained by heating slowly and uniformly in a freely circulating medium. If a liquid is used, the tools should be placed in a metal basket for immersion which prevents contact with the sides or bottom of the tempering pot.

Charging the Tempering Furnace—When charging tools for tempering, the heating medium should be at a low temperature and the tools still warm.

Rate of Heating—Tools should be brought to heat slowly to prevent rapid release of hardening strains and warpage. Better results are obtained by holding at a lower temperature for a longer time. Generally the length of time should not be less than 1 hr. at temperature, but for specific steels reference should be made to the tool steel articles in this Handbook.

Rate of heat transfer will vary in different heating media. It is most rapid in metallic baths, less rapid in salt and oil baths, and still less in circulated and slowest in still air furnaces.

Cooling from Tempering—Cooling from the tempering operation should be in still air because rapid cooling may induce strains in the steel.

Tempering by Color—Temper colors are the result of slight oxidation of the surface of steel when heated at low temperatures, and are dependent upon time, temperature, and composition of the steel. They are only indicative of the temperature of the surface and do not indicate that the steel has been heated uniformly throughout. Tempering by color is not conducive to uniformity. When necessity requires that tools be tempered by color they should be heated slowly as in other operations and the heat raised progressively to the point or color desired after which further tempering is usually stopped by quenching or withdrawing from the heating medium. The quenching should be done in the least drastic manner, preferably in oil.

General Notes—Warping—The amount of warping on hardening is dependent on the shape of the tool, the kind of steel, the conditions of heating, and the severity of the quench. In general, water hardening steels warp more than oil hardening, whereas air hardening steels show least distortion. Long, thin tools warp more than short, heavy ones.

Some causes of undue warpage are improper tool design, the use of the wrong type of steel, nonuniform or too rapid heating, improper support of the steel while heating, heavy machining or cold working strains (see strain relieving annealing under annealing) insufficient removal of surface, nonuniform quenching, and non-uniform or too rapid tempering.

Soft Spots—Common causes of soft spots are decarburization; improper heating, quenching or bath agitation; gas pockets; tong contact; adhering scale; insufficient removal of surface; or defective furnace bottoms.

Straightening—When necessary to straighten the operation is best performed on the descending heat. Straightening is done by peening, or bending in a vise or on a suitable press with an adjustable control and knife edge rests, so that if one load does not satisfactorily straighten the tool another load can immediately be applied. For straightening on the descending heat, the tools should be withdrawn from the bath at a temperature from 500-600°F., which is just below the point where the oil ceases to flash, or in the case of water quenched tools, just where the water steams or dries off the tools immediately.

Composition and Heat Treatment of Carbon Tool Steels*

(See also the General Heat Treatment article for Tool Steels, page 987.)

General—This article covers the process to be followed in the heat treating of carbon tool steel for general purposes. For specific types of tools refer to the articles in this Handbook for the particular tool in question.

Composition and Application—Carbon tool steel hardens with a hard case and tough interior except in small sizes. By varying the carbon content a wide range of physical properties may be obtained. These factors make it suitable for a great many applications. Thus the lower carbon ranges are used for tools where toughness and resistance to shock are of primary importance, and the higher carbon where hardness, resistance to abrasion, or ability to hold a keen edge are the main requirements.

The type analyses are given in Table I and the range for the carbon content and a few of the more common applications for the steels covered in this article are as follows:

Carbon Content 0.60-0.75%—Hot forming or heading dies for short runs; machinery parts; hammers (sledges and pinch bars); concrete breakers; rivet sets.

Carbon Content 0.75-0.90%—Hot and cold set, chisels, dies, shear blades, mining drill steel, smith's tools, set hammers, swages, flatteners.

Carbon Content 0.90-1.10%—Small cold chisels, small shear blades, large pinchers, large taps, granite drill steel, trimming dies, drills, cutters, slotting and milling tools, mill picks, circular cutters, threading dies.

Carbon Content 1.10-1.25%—Small cutters, small taps, drills, slotting and planing tools, wood cutting tools, turning tools, razors.

Forging—Temperatures for forging are given in Table II. For thin sections use the lower temperature range and for thick sections the higher. Continue forging until a dark red color is reached and then cool slowly in lime or mica.

Table I
Approximate Chemical Composition

Steel No.	C	
1.	0.85	The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Table II
Forging, Normalizing, and Annealing Carbon Tool Steels

Steel No.	Forging ^a			Normalizing After Forging			Annealing ^b		
	Start °F.	Do Not Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1. ...	1800-2000	1500	Slowly to 1450	1600	Slowly to 1450	15-60	1360-1400	Slowly and Uniformly	1-4
2. ...	1800-2000	"	"	1550-1650	"	"	1400-1440	"	"
3. ...	1800-2000	"	"	1600-1700	"	"	1400-1440	"	"

^aThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bCooling rate of 50° max. per hr. to 1000°F.

Normalizing—Place the steel in a furnace so as to expose maximum surface area. Heat uniformly to the temperature given in Table II, and hold at this temperature for sufficient time to obtain complete penetration of heat and for complete solution of the cementite.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerasen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Carbon tool steels in larger sections should be heated at the rate of $\frac{1}{4}$ -1 hr. per in. of dia. or thickness and should be held at the normalizing temperature approximately $\frac{1}{4}$ to $\frac{1}{2}$ of the heating time. After properly heating, remove the steel from the furnace and cool in air.

Fig. 1—Hardness of a 0.90% or higher carbon tool steel after tempering.

erably a brine solution of 10% by weight held at a temperature of 70-80°F. Remove the tool from the bath while still warm, but not before it has cooled to about 200°F.

The temperatures in Table III are an average for most tools. Small or intricate sections are quenched from the lower side of the range. A fully hardened carbon steel tool of 0.90% carbon or higher will have a Rockwell C hardness of 64-67 as shown in Fig. 1.

Table III

Heat Treatments for Carbon Tool Steels

Steel No.	Rate of Heating for Hardening	Hardening Temp., °F.	Quenching Medium	Tempering Temp., °F.
1.	Slowly	1450-1500	Brine or Water	300-550
2.	"	"	"	"
3.	"	1400-1475	"	"

Tempering—After quenching, reheat immediately and uniformly to the temperature specified in Table III and Fig. 1. Hold at the temperature for at least 1 hr. then cool in still air.

Suitable Tempering Heats for Various Tools—Temperatures—300-375°F.—Lathe tools for brass and copper alloys, milling cutters for brass and copper alloys, scraper and cutting tools for soft metals, drawing mandrels, drawing dies, bone cutting tools, steel engraving tools, cutting tools for iron and steel, threading dies for brass, gages.

Temperature—375-500°F.—Hand taps and dies, hand reamers, drills, bits, cutting dies, penknives, milling cutters, chasers, inserted sawteeth, press dies for blanking and forming, rock drills, taps and dies, dental and surgical instruments, twist drills, hammer faces, wood carving tools, forming dies, shear blades, reamers, hacksaws.

Temperature—500-650°F.—Bending dies, shear blades, chuck jaws, forging dies, drifts, tools for wood cutting, hammers and drop dies, axes, cold chisels, coppersmith tools, screw drivers, molding and planing tools, hacksaws, butcher knives, saws.

Notes About the Process

Normalizing—A normalizing treatment for all carbon tool steels is recommended after forging and before annealing to obtain a uniform and refined grain structure.

The variation in temperature for the different carbon ranges becomes evident upon a careful examination of the critical range diagram, Fig. 2. A temperature much in excess of that required to produce solid solution (austenite) is conducive to austenitic grain growth and intergranular weakness.

A low normalizing temperature for high carbon steels (1.25-1.50% carbon) fails to break up the massive cementite and results in a brittle structure, since the rate of diffusion of the excess cementite depends upon the temperature. The solubility of carbide in iron is greater as the temperature rises.

Quenching—The quenching temperatures given are average for most tools. Small or intricate sections are quenched from the lower side of the range. Some classes of tools, however, require higher temperatures, such as cold heading and cold striking dies.

The quenching temperature influences the hardness, penetration and final grain size. As these affect markedly the physical properties, uniformity of die life can not be obtained if the quenching temperature is not closely controlled. As absolute uniformity of heating is obtainable only in theory, the best practice is to use temperatures above the A_c critical range as shown in Fig. 1.

Brine or water is the customary quenching medium for carbon tool steels. For details on quenching see the General Heat Treatment Article for Tool Steels.

Microstructure—The microstructure of the annealed steel should consist of carbide particles of a uniform and small size in a background of ferrite. It may or may not contain areas of pearlite not exceeding 25%. It must be free from large carbide particles in the network form. When tools are forged and subsequently normalized and annealed, full consideration should be given to producing the correct microstructure.

Fig. 2—Critical range diagram for iron-carbon alloys, showing normalizing, annealing, and hardening ranges.

Composition and Heat Treatment of High Carbon, High Chromium Steels*

(See also the General Article on Page 987.)

General—Three general types of high carbon, high chromium steel exist, as indicated in Table I. A large number of steels of individual character may be manufactured and still conform, within reasonable limits, to those listed. When the composition of steels conforms within reasonable limits, the heat treatment will be as recommended, even though properties vary.

Steels of Type 1 class are essentially oil hardening. Types 2 and 3 may be hardened either in still air or by oil quench. These steels are subject to more or less carbide segregation, even to a greater extent than high speed steels, and they are inherently rather brittle particularly in large size sections. Both types are valuable for their remarkable wear resisting properties and low movement in hardening. The air hardening types are tougher and more readily machinable but steels of Type 1 have higher wear resisting properties. The uses of all three classes are somewhat interchangeable. Type 1 should be selected when resistance to wear is of greatest importance and Types 2 or 3 where machinability or toughness is required in conjunction with high wear resistance. The steels are well suited for tools such as blanking, forming and trimming dies, deep drawing dies, wire drawing dies, plug gages, burnishing broaches, thread rolling dies, wood working knives, shear blades, and lathe centers.

Forging—If heated too rapidly or to too high temperature, these steels tend to become hot short. They should be preheated slowly to 1600°F., and soaked thoroughly at the recommended forging temperature. Forging should begin with light blows until the steel has started to flow. Reheat as often as necessary to keep within temperature range recommended in Table II.

Fig. 1—Hardness and tempering curves for high carbon, high chromium steels.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stolz, Chairman, A. S. Jameson, A. J. Scheld, Jr., G. V. Luerksen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spaulding.

2	1800-1900*	"	"	" "	" "	"	"
3	1800-1900*	"	"	" "	" "	"	"

*After forging bury in lime or mica for slow cooling. Do not normalize.

^bThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

Annealing—A Brinell hardness of 228 may be considered good for annealed high carbon, high chromium steels. Pack annealing will assist in obtaining lowest hardness results. Since all of the types tend to decarburize on heating, the use of new cast iron chips or charcoal is suggested. Heat uniformly to the temperature recommended in Table II, and hold 1-4 hr., depending on size of charge. Cooling should be done in the furnace at a maximum rate of 50°F. per hr. to 1000°F. Below 1000°F. a faster rate may be used, if desired.

Hardening—All high carbon, high chromium steels tend to decarburize unless heated in specially designed furnaces having properly controlled atmospheres. To prevent decarburization, pack hardening methods are used. Charcoal will carburize at the temperatures recommended in Table III, but may be satisfactory for some types of tools and dies. Where edge strength is desired, spent pitch coke should be used in place of charcoal. Absorption of heat and diffusion of carbides is much slower with these steels than with low alloy tool steels. They should be preheated to 1500°F. and held for complete uniformity, then transferred to the quenching temperature. Soak at the quenching heat will vary with size of dies, but should be about 3 times as long as would be used for similar sized carbon tool steel.

The quenching temperatures recommended in Table III are best adapted for dies and tools because of improved strength resulting from better grain refinement. However, attention is called to the hardness curves obtainable from temperatures in the neighborhood of 2000°F. (Fig. 1). Austenite retained on quenching from this high temperature produces secondary hardening as it transforms in subsequent tempering at about 1000°F. The high quenching temperature may be valuable for

Table III
Heat Treatments for High Carbon High Chromium Steels

2	"	"	1700-1800	"	Oil	
			1800-1900	"	Air	400-1000
3	"	"	1800-1900	"	Air	400-1000

^aSome people believe it is undesirable to temper these steels between 600-800°F.

use on dies that must resist heat. It is also used if dies or tools are to be nitrided after hardening. High carbon, high chromium steels are readily nitrided either in the ammonia gas process or by tempering at 1000°F. in cyanide bath mixtures.

Tempering—The tempering curves (Fig. 1) indicate hardness obtainable from various temperatures. Tempering below 400°F. is rarely advisable because of the lack of toughness at the lower range. These steels should be heated slowly to the desired temperature to prevent cracking.

Notes—High carbon, high chromium steels often fail in a manner differing from low alloy or carbon tool steels. Where these steels generally require regrinding because of becoming dull, the high carbon, high chromium steels may wear so long that fatigue strains develop and chipping of edges results. In redressing tools or dies after such failure it is advisable to anneal, remachine and reharden, rather than resort to grinding. This treatment will remove fatigue strains and restore new life to the steel.

These steels are difficult to grind in the hardened condition because of their high resistance to abrasion. Unless proper grinding wheels are used heat checks may form. Soft wheels of self dressing character are recommended.

Composition and Heat Treatment of "Nonshrinking" Oil Hardening Tool Steels*

(See also the General Heat Treatment article for Tool Steels, Page 987.)

General—This article covers the heat treatment of the so-called nondeforming, oil hardening tool steels of the types listed in Table I.

Table I
Approximate Chemical Composition*

Steel No.	C	Mn	W	Cr	V
1	0.90	1.10	0.50	0.50	0.20 Opt.
2	0.90	1.60			
3	1.15	0.30	1.60	0.50	0.20

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Application—These oil hardening steels are used for general tools and dies whose design prohibits the use of water hardening steels because of the hazard of distortion or cracking during hardening. They do not usually hold their dimensions as closely as the air hardening type of high carbon, high chromium tool steels.

These steels are relatively deep hardening and are often selected where this is an advantage. In fully hardened small sections, they give around C-65 Rockwell, but as the size of the section increases, the hardness decreases.

Forging—Heat slowly and uniformly to the forging temperature given in Table II. If cold steel is charged in a hot furnace, or if it is heated too rapidly, it may be cracked, especially if unannealed. The steel must be uniformly heated through before being forged, and reheated as often as necessary during forging to keep it within the temperature range given.

The steel should become black before charging in a normalizing furnace.

Normalizing—Always normalize after forging at the temperatures given in Table II. Steel annealed at the mill does not require normalizing unless subsequently forged.

Table II
Forging, Normalizing, and Annealing of Nonshrinking Oil Hardening Steel

Steel No.	Forging ^a			Normalizing After Forging			Annealing ^b		
	Start °F.	Do Not Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1	1800-1950	1600	Slowly to 1500	1650	Slowly to 1500	15-60	1425-1450	Slowly and Uniformly	1-4
2	1800-1900	1600	Slowly to 1500	1550	Slowly to 1500	15-60	1400-1425	Slowly and Uniformly	1-4
3	1800-1950	1600	Slowly to 1500	1700	Slowly to 1500	15-60	1450-1475	Slowly and Uniformly	1-4

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bCooling rate 50° max. per hr. to 1000°F.

Annealing—Heat slowly and uniformly to the temperatures given in Table II. Hold at temperature for sufficient time to obtain complete penetration of heat and refinement of grain. Machining strains may be relieved by a subcritical anneal at 1200°F.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, M. T. Cousins, J. A. Succop, A. D. Becken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Hardening—In order to hold distortion to a minimum and to get maximum and uniform hardness, it is advisable to preheat slowly and uniformly at about 1200°F. Then bring up to the hardening temperatures given in Table III. Type No. 2 should be quenched as soon as uniformly heated through—not soaked thereafter. Types 1 and 3 should be soaked a short time at the hardening temperature, in proportion to the size of the piece, before quenching, in order to obtain maximum hardness. Do not soak for minimum distortion.

Table III

Heat Treatments for Nonshrinking Oil Hardening Tool Steels

Steel No.	Preheat Temp. °F.	Rate of Heating For Hardening	Hardening Temp. °F.	Time at Heat	Quenching Medium	Tempering Temp. °F.
1	1200	Slowly	1450-1500	½ hr. for max. hardness*	Oil	325-500
2	1200	Slowly	1400-1475	Do not soak	Oil	325-500
3	1200	Slowly	1575-1625	½ hr. for max. hardness*	Oil	350-550

*No soak for minimum distortion.

If the tool is of intricate design or has abrupt and extreme change of section, it is of great importance to heat slowly in order to prevent breakage and reduce warpage.

Quench in a good quenching oil, the temperature of which should be 100-125°F., but do not cool the steel below the temperature of boiling water.

Tempering—Reheat immediately to the tempering temperature given in Table III.

Notes About the Process—These steels are essentially oil hardening, and over heating of the oil during prolonged and continuous quenching should be avoided. The ratio of bath volume to mass of steel is an important factor. There must be plenty of oil in the bath.

When using a furnace where atmosphere control is possible a slightly oxidizing atmosphere is recommended as a help in preventing "skin softness." If hardening is done in a furnace employing an atmosphere of cracked oil, care must be exercised not to drop the oil too fast or carburization of the surface will result.

The edges and corners of any piece of steel always harden more readily than large flat areas because the cooling medium extracts the heat faster. This is particularly noticeable with fairly large sections of oil hardening steel. In order to crack off the scale and harden the broad, flat surfaces properly, it is advisable to force plenty of oil, usually by means of a pump under good pressure, against these surfaces, and to use the top side of the hardening range.

Composition and Heat Treatment of Tungsten Finishing Steels*

(See also the General Heat Treatment Practice for Tool Steels, page 937.)

General—This article covers the heat treatment of a steel commonly known as tungsten finishing steel, or fast finishing steel.

Composition—There are various minor modifications of composition of tungsten finishing steels. However, the following is typical of the class: C 1.30%; W 3.75%; and Cr 0.25 (optional).

Application—Steels conforming to the above analysis are particularly adapted to finishing cuts where unusually smooth finish is required and for cold drawing dies. The tungsten gives exceptional hardness after water quenching. The extremely hard tungsten carbide particles uniformly distributed throughout the matrix produces great resistance to wear. The combination of hardness and resistance to wear makes this steel suitable for the following applications: Burnishing tools; chilled roll turning tools; cold extrusion dies; corrugating tools; tools for cutting brass, chilled cast iron, hard bone, ivory, marble; dental burrs; drawing dies; fine finishing lathe tools, and rifling tools.

This steel does not possess the red hardness properties characteristic of high speed steels.

Forging—Heat very slowly and uniformly to 1550° and then raise temperature to 1850-1950°F. before starting to forge and finish not below 1600°F. After the forging has been completed, the cooling should be retarded by the use of some insulating material. Do not normalize.

Annealing—Heat thoroughly to 1450-1500°F. and hold at this temperature for a sufficient length of time to insure complete penetration of heat, follow by slow cooling in furnace.

Hardening—Preheat thoroughly at 1200-1300°F., raise the steel to a temperature of 1450-1550°F. Hold at temperature for sufficient time to insure thorough penetration; quench in either brine or water at approximately 70°F. If the lower side of the hardening range is used, it is necessary to hold the steel at temperature for 15-30 min. longer to obtain full and uniform hardness.

Tempering—Following the hardening operation the steel should be removed from the quenching medium while it is still warm and tempered immediately. The tempering temperature varies according to the hardness desired. With a steel similar to the above composition the hardness after quenching from 1600°F., and after tempering should be about as follows:

Rockwell C hardness	
As Quenched	66-68
Tempered, 300°F.	64-66
" 350°F.	64-66
" 400°F.	63-65
" 500°F.	61-63
" 600°F.	59-61

The size and hardening conditions may cause a slight variation from these figures.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Composition and Heat Treatment of Tungsten High Speed Steel Cutting Tools*

(See also the General Heat Treatment Article for Tool Steels, page 987.)

General—This article covers the heat treatment of 18-4-1, 18-4-2, and the 14% tungsten high speed steels.

Composition—The approximate chemical compositions for the three types of high speed steel considered are given in Table I.

Table I
Approximate Composition of 18-4-1, 18-4-2, and 14% Tungsten High Speed Steel^a

Steel No.	C	W	Cr	V	Mo
1	0.70	18	4.00	1.00	
2	0.80	18	4.00	2.00	0.70
3	0.75	14	4.00	2.00	0.50 Opt.

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Application—These three high speed steels are used for all classes of cutting tools on all types of materials to be cut.

Forging—For forging, heat slowly and uniformly to a temperature given in Table II. It is not safe to continue forging below 1700°F. Slow cooling after forging is necessary to prevent possible cracking from forging strains.

Table II
Forging and Annealing Tungsten High Speed Steel Cutting Tools

Steel No.	Forging ^c			Annealing ^d			
	Start °F.	Do Not Forge Below °F.	Rate of Heating	Temp. °F.	Rate of Heating	Time at Heat, hr.	Rate of Cooling
1 ^a	2050-2150	1700	Slowly to 1600	1600-1650	1 hr. per in. max. thickness	1-4	50° per hr. max. to 1000°F.
2 ^a	2050-2200	1700	Slowly to 1600	1600-1650	Slowly and Uniformly	1-4	50° per hr. max. to 1000°F.
3 ^a	2000-2100	1700	Slowly to 1600	1600-1650	1 hr. per in. Slowly and Uniformly	1-4	50° per hr. max. to 1000°F.

^aAfter forging cool slowly in lime or mica.

^cThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^dDo not normalize these steels.

Annealing—All high speed steel should be annealed after forging and before hardening or when rehardening is required. Box annealing is always preferable. When annealing partially finished tools and generally when surface protection is of prime importance, it is recommended that cast iron chips be used for packing materials.

Heat slowly and uniformly to 1600-1650°F. and hold for complete adjustment and uniformity of grain. Cool in furnace at a maximum rate of 50°F. per hr., until the steel is below 1000°F. The steel should not be taken from the furnace until it is below 1000°F.

After machining and before hardening, it may be necessary to relieve harmful machining strains by annealing at 1200-1350°F.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Willa, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Preheating, Heating for Hardening, and Quenching—Preheating—Preheat slowly and uniformly to 1450-1600°F. When hardening large tools or when distortion must be held to a minimum, it is essential to preheat very slowly and uniformly. To accomplish this, it is often advisable to use two preheating furnaces, one held at 1100-1200°F. the other at 1450-1600°F.

Heating for Quenching—Transfer preheated tool quickly to a high heat furnace that is maintained at the temperature given in Table III.

Table III .

Heat Treatments for Tungsten High Speed Steel Cutting Tools

Steel No.	Preheat Temp., °F.	Hardening Temp., °F.	Quenching Medium	Tempering Temp., °F.
1	1450-1600	2250-2350	Oil, Air or Molten Bath	1000-1150
2	1450-1600	2300-2350	Oil, Air or Molten Bath	1000-1150
3	1450-1600	2200-2300	Oil, Air or Molten Bath	1000-1150

In order to obtain the most satisfactory condition, the tool should be brought rapidly to heat in the high temperature furnace. High speed steel tools should be held at high heat sufficient time for proper solution of the carbides without an excessive grain growth or damage to the surface. This should be measured in minutes and seconds.

Quenching—Quench the tool in oil, air, or molten bath. To reduce the possibility of breakage and undue distortion in intricately shaped tools, it is advisable to quench in a molten bath at approximately 1100°F. The tool may be quenched in oil and removed from the bath while still red or at approximately 1100°F. The tool is then cooled slowly in air to 200-300°F., then temper immediately to avoid cracking.

Tempering—Reheat slowly and uniformly to 1025-1150°F. Hold at temperature from 1-4 hr.; the time and temperature depend on the hardness and toughness required.

Straightening—When straightening is necessary, it should be done, if possible, immediately after hardening and before the steel has cooled much below 900°F. If straightening has to be done after tempering the steel should not be allowed to cool much below the tempering temperature.

Notes About the Process—Atmosphere Controlled Furnaces—Atmosphere controlled furnaces satisfy a demand for more accurate dimensional control and a surface not injured during heating for hardening. These furnaces are now available in both electric and fuel fired types where the atmosphere is independent of the source of heat. This permits control of the atmosphere in contact with the work. Small and delicate pieces can be given the heat treatment that will develop the best physical properties of the steel without materially injuring the surface or overheating thin projections.

The ideal atmosphere would be one that is neutral to the steel. The atmospheres now used are the products of combustion of partly burned fuel. They may be cleaned of undesirable constituents and closely regulated as to composition. The best conditions are generally obtained when the hardened steel shows a slightly oxidized surface. Suitable atmospheres will vary with different fuels and equipment. A gas analysis apparatus will help in determining the correct atmosphere.

Salt Bath—With tools that cannot be ground after hardening, or where it is necessary to keep the surface in the best possible condition and preserve sharp edges, salt bath heating will give the best results. The only appreciable change in dimensions will be that of expansion or contraction caused in quenching the tool or by the change in structure of the steel in hardening.

Certain precautions are necessary when using salt baths. Fresh salt has a dissolving action on the steel which disappears after the bath is used a short time. As the bath gets older, a sludge is formed at the bottom of the pot and a heavy crust at the top; these must be removed periodically. As the bath becomes excessively contaminated, pitting, soft surface, or loss of size will occur. An experienced operator can produce satisfactory work by the proper addition of new salt and by avoiding excessive contamination.

Composition and Heat Treatment of Molybdenum High Speed Steel*

(See also the General Heat Treatment Practice for Tool Steels, page 987.)

General—This article covers the heat treatment of high speed steels in which molybdenum is the principal alloying element. The molybdenum high speed steels are relatively new as regards their industrial use, and their chemical compositions are not as definitely established as the 18-4-1 type. These steels decarburize more readily than tungsten types, but with reasonable precautions in heating for forging and hardening this disadvantage can be overcome.

Composition—The approximate chemical compositions of the molybdenum high speed steels considered in this practice are given in Table I.

Table I
Approximate Composition^a of Molybdenum High Speed Steels

Steel No.	C	W	Cr	V	Mo	Co
1	0.80	1.50	4.00	1.00	9.00	
2	0.80		4.00	2.00	9.00	
3	0.80	1.50	4.00	1.50	9.00	5.00

^aThe analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Application—Types 1 and 2 are adapted for most cutting tool applications where a general purpose high speed steel is required. Hardness and toughness compare favorably with tungsten high speed steels. Type 3 is inherently more brittle than 1 and 2, and applications are more limited than the other types.

Forging—These steels can be forged like the tungsten types but at slightly lower temperatures, and some precautions should be taken to prevent excessive decarburization during the heating cycle. (See notes about the Process, below).

For forging, heat slowly and uniformly to a temperature given in Table II. Avoid prolonged soaking at the forging heat and too little reduction. After forging it is desirable to cool slowly down to about 300°F. to avoid possible cracking from forging strains.

Table II
Forging, and Annealing Molybdenum High Speed Steel

Steel No.	Forging ^a			Annealing ^c			
	Start °F.	Do Not Forge Below °F.	Rate of Heating	Temp. °F.	Rate of Heating	Time at Heat, hr.	Rate of Cooling
1 ^a	1900-2000	1650	Slowly to 1500	1550-1600	Slowly and Uniformly 1 hr. per 1 in.	1-4	Max. 50 per hr. 1000°F.
2 ^a	1900-2000	1650	Slowly to 1500	1550-1600	Slowly and Uniformly 1 hr. per 1 in.	1-4	Max. 50 per hr. 1000°F.
3 ^a	1900-2000	1650	Slowly to 1500	1550-1600	Slowly and Uniformly 1 hr. per 1 in.	1-4	Max. 50 per hr. 1000°F.

^aAfter forging cool slowly in lime or mica.

^bThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^cDo not normalize these steels.

Annealing—Like tungsten high speed steels, these steels should be annealed after forging and before hardening, or when rehardening is required.

Box annealing is always preferable. When annealing partially finished tools,

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheld, Jr., G. V. Luerssen, W. H. Willis, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. F. Howley, H. A. Anderson and S. C. Spalding.

and generally when surface protection is of prime importance, it is recommended that cast iron chip be used for packing material.

Heat slowly and uniformly to the temperature given in Table II and hold for complete adjustment and uniformity of grain. The steel should not be taken from the furnace until it is below 1000°F.

After machining and before hardening it may be necessary to relieve harmful machining strains by annealing at 1200-1350°F.

Hardening—The general method of hardening molybdenum high speed steels resembles that followed with 18-4-1, but the hardening temperature (Table III) is lower and more precautions must be taken to avoid decarburization, especially on tools where the surface is not ground after hardening. Salt baths represent an excellent type of equipment for hardening molybdenum high speed steel. (See below.) The use of coke fires or the blacksmith forge is not recommended for hardening molybdenum high speed steels. Tools that have been forged should be machined or rough ground after annealing to remove possible surface defects and reduce the grinding necessary after hardening.

Table III
Heat Treatments for Molybdenum High Speed Steels

Steel No.	Preheat Temp. °F.	Hardening Temp. °F.	Quenching Medium	Tempering Temp. °F.
1	1400-1500	2150-2250	Oil, Air and Molten Bath	950-1100
2	1400-1500	2150-2250	Oil, Air and Molten Bath	950-1100
3	1400-1500	2200-2250	Oil, Air and Molten Bath	950-1100

Preheating—Preheat slowly and uniformly to 1400-1500°F., using the upper part of the range for larger sections. When hardening large tools or when distortion must be held to a minimum, slow preheating may be insured by the use of two preheating furnaces, one held at 1100-1200°F. and the other at 1400-1500°F.

Heating for Quenching—Transfer preheated tool quickly to a high heat furnace that is maintained at 2150-2250°F. The exact temperature depends on the type of tools, the hardening range of the steel, and the furnace atmosphere. In order to obtain the most satisfactory condition, the tools should be brought rapidly to heat in the high temperature furnace and should be held for a sufficient time for proper solution of the carbides without excessive grain growth. Factors affecting this time are temperature, type of furnace, size and shape, and furnace atmosphere. Rate of heat transfer is most rapid in salt baths, and slowest in controlled atmosphere furnaces (see below).

Quenching—Quench the tool in oil, air, or molten bath. To reduce the possibility of breakage and undue distortion in intricately shaped tools, it is advisable to quench in a molten bath at approximately 1100°F. The tool may be quenched in oil and removed from the bath while still red or at approximately 1100°F. The tool is then cooled slowly in air to 200-300°F., then tempered immediately to avoid cracking.

Straightening—When straightening is necessary, it should be done before tempering and, if possible, before cooling to room temperature.

Tempering—Reheat slowly and uniformly to 950-1100°F. Hold at temperature from 1-4 hr.; the time and temperature depend on the hardness and toughness required.

Notes About the Process

Protection of Surfaces During Heating—Due to the tendency of molybdenum high speed steels to decarburize when heated to the forging or hardening temperature range, the use of a borax film or proper furnace atmosphere is helpful in minimizing the decarburization. Borax may be applied by lightly sprinkling over the steel when heated to a low temperature (1000-1400°F.). When a reheat is necessary during forging, more borax should be applied. Small tools heated as above may be rolled in a box of borax.

Another method more suitable for finished tools is to apply the borax in the form of a saturated water solution. In such cases the unheated tools are immersed in the solution at 180-212°F., or it may be applied with a brush or spray. Pieces so treated are heated as usual with care taken in the handling not to scrape off the borax.

When borax is used in a furnace with a Carborundum bottom it is necessary to use a metal pan, preferably of stainless iron, to prevent the borax from fusing with the Carborundum. Such fusion produces a glass like insoluble coating on the tool which is impossible to remove without damage to the cutting edge.

Atmosphere Controlled Furnaces—Atmosphere controlled furnaces satisfy a demand for more accurate dimensional control and surface protection. These furnaces are now available in both electric and fuel fired types where the atmosphere is independent of the source of heat. This permits control of the atmosphere in contact with the work. Small and delicate pieces can be given the heat treatment that will develop the best physical properties of the steel without materially injuring the surface or overheating thin projections.

The ideal atmosphere would be one that is neutral to the steel. The atmospheres now used are the products of combustion of partly burned fuel. They may be cleaned of undesirable constituents and closely regulated as to composition.

The best conditions are generally obtained when the hardened steel shows a slightly oxidized surface. Suitable atmospheres will vary with different fuels and equipment. A gas analysis apparatus will give help in determining the correct atmosphere.

Another method of producing an atmosphere that protects the surface is to heat the tools in a block or muffle of a suitable carbonaceous material. At the hardening temperature an atmosphere high in carbon monoxide is generated. To maintain uniformity, however, the size of the muffle is limited and this method is adapted only to small tools.

Salt Bath—With tools that cannot be ground after hardening, or where it is necessary to keep the surface in the best possible condition and preserve sharp edges, salt bath heating will give the best results. The only appreciable change in dimensions will be that of expansion or contraction caused in quenching the tool or by the change in structure of the steel in hardening. The equipment usually consists of at least three baths—the preheat, high heat, and quenching bath—the function of the latter being to dissolve the high temperature salt from the work so as to facilitate cleaning.

Certain precautions are necessary when using salt baths. Fresh salt has a dissolving action on the steel which disappears after the bath is used a short time. As the bath gets older, a sludge is formed at the bottom of the pot and a heavy crust at the top; these must be removed periodically. As the bath becomes excessively contaminated, pitting, soft surface, or loss of size will occur. An experienced operator can produce satisfactory work by the proper addition of new salt and by avoiding excessive contamination.

Composition and Heat Treatment of Cobalt High Speed Steels*

(See Also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the process to be followed in the heat treatment of cobalt high speed steels.

The composition of the steels as given in Table I covers practically the entire range of cobalt high speed steels now in general use. Cobalt high speed steels not included in Table I may require different heat treatment.

Table I
Approximate Composition of Cobalt High Speed Steels*

Steel No.	C	W	Cr	V	Mo	Co
1	0.75	14	4.00	2.00	0.50	5.00
2	0.70	18	4.00	1.00	0.50	5.00
3	0.80	20	4.00	2.00	0.50	8.00
4	0.80	20	4.00	1.25	0.50	12.00

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Application—Cobalt high speed steels are particularly adapted for cutting hard, gritty or scaly material, such as cast iron, heat treated steels, or sand castings. They do not show the same increased efficiency in the cutting of soft materials as when cutting comparatively hard materials.

Forging—Heat slowly and uniformly to the temperature given in Table II. Do not forge these steels after they have cooled below 1650°F. as cracking may result. After forging, the steel should not be allowed to cool in air but should be buried immediately in some heat insulating material so as to cool slowly, otherwise forging strains may cause cracks in cooling. These steels must be annealed after forging.

Table II
Forging and Annealing Cobalt High Speed Steels

Steel No.	Forging ^a			Annealing ^b			
	Start °F.	Do not Forge Below °F.	Rate of Heating	Temp. °F.	Rate of Heating	Time at Heat	Rate of Cooling
1	2050-2150	1700	Slowly to 1600	1600-1650	Slowly and Uniformly	1-4 hr.	50° Max./hr.
2	2050-2150	1750	Slowly to 1600	1600-1650	Slowly and Uniformly	1-4 hr.	50° Max./hr.
3	2100-2200	1800	Slowly to 1600	1600-1650	Slowly and Uniformly	1-4 hr.	50° Max./hr.
4	2100-2200	1800	Slowly to 1600	1600-1650	Slowly and Uniformly	1-4 hr.	50° Max./hr.

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bDo not normalize these steels.

Annealing—Pack in a suitable container with mica dust or sand to which has been added approximately 1% of charcoal by weight. Heat to a temperature given in Table II and hold until the heat has thoroughly penetrated the mass. Cool in the furnace as slowly as possible.

Hardening

Preheating—Heat slowly and uniformly to a temperature of 1500-1600°F. Hold at this temperature until the steel is thoroughly heated through and transfer to the high temperature furnace. These steels decarburize readily if held too long at or above the preheating temperature.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stots, Chairman, A. S. Jameson, A. J. Scheld, Jr., G. V. Luerasen, W. H. Willis, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Where large tools are to be hardened, a double preheat is often desirable. The first preheating temperature is 1150-1300°F. and the second preheating temperature is 1600-1700°F.

High Heat—After being transferred to the high temperature furnace, steel No. 1 should be heated quickly to the hardening temperature of 2325-2375°F., while types No. 2, 3 and 4 should be heated to a hardening temperature given in Table III. As soon as the steel has reached this temperature it should be immediately quenched. Prolonged soaking will cause excessive decarburization and some grain growth.

Table III
Heat Treatments for Cobalt High Speed Steels

Steel No.	Preheat Temp. °F.	Hardening Temp. °F.	Quenching Medium	Tempering Temp. °F.
1	1500-1600	2325-2375	Oil, Air, Molten Bath	1000-1150
2	1500-1600	2350-2400	Oil, Air, Molten Bath	1000-1150
3	1500-1600	2325-2375	Oil, Air, Molten Bath	1000-1150
4	1500-1600	2325-2375	Oil, Air, Molten Bath	1000-1150

Quenching—These steels may be quenched in either still air, air blast, or oil, depending upon the size and design of the tool being hardened. They should be cooled to a temperature under 300, but not below 100°F. Unless equipment is available to keep the tools at a temperature within this range they should be tempered immediately. These steels also may be quenched in molten salt or lead maintained at a temperature of from 1000-1100°F. When quenched in a salt or lead bath the tool is allowed to remain in the bath for from 15-30 min., then removed and allowed to cool in still air. Tools treated in this manner are subject to the same tempering recommendations as when they are cooled in air or oil.

Tempering—To obtain maximum hardness, these steels should be tempered to 1050°F. and held at this temperature from 1-3 hr., depending on size. A second tempering, of from 600-650°F., will toughen these steels without materially affecting the initial hardness.

Surface Decarburization and Grinding—All cobalt high speed steels show a tendency to decarburize during the hardening operation in approximately direct proportion to the cobalt content. Because of this characteristic it is always advisable to grind the working surface of the steel after hardening. It is strongly recommended that the steel be ground after forging and annealing and before hardening to remove any decarburized surface that may have resulted from the forging heat. This precaution will lessen the amount of decarburization.

It is important that the proper grade and speed of wheel be used when grinding a hardened tool, since with too hard or fine a wheel or with too high speed there is pronounced danger of cracking in grinding. Wet grinding is not generally recommended but may be applied successfully with proper equipment. In dry grinding care must be taken not to dip tools into water to cool, because such practice will result in cracking or checking the tools.

Composition and Heat Treatment of Chisels*

(See Also the General Heat Treatment Article for Tool Steels, Page 987.)

General—Chisels must meet severe fatigue stresses and retain good cutting edges. Various steels as well as heat treatments are employed to meet these conditions. Only the principal steels and simpler treatments are given here.

Table I
Approximate Chemical Composition^a

Steel No.	C	Mn	Si	W	Cr	V	Mo
1	0.80						
2	0.80					0.20	
3	0.50				0.80	0.20	
4	0.60				0.50		
5	0.50			2.00	1.25	0.25	
6	0.55	0.80	2.00		0.50 Opt. (max.)	0.25 Opt. (max.)	0.30 Opt. (max.)
7	0.50	0.40	1.00			Opt.	0.50

^aThe analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Table II
Forging, Normalizing, and Annealing Chisels

Steel No.	Forging ^b			Normalizing After Forging ^c			Annealing ^c		
	Start °F.	Do not Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1	1800-2000	1500	Slowly to 1450	1600	Slowly to 1450	15-60	1360-1400	Uniformly	1-4
2	1800-2000	1500	"	1600	"	15-60	1360-1400	"	1-4
3	1800-2000	1600	"	1650	"	15-60	1425-1450	"	1-4
4	1900-2100	1600	"	1600	"	15-60	1425-1450	"	1-4
5 ^a	1850-1950	1550	"	— Do not normalize —			1450-1500	"	1-4
6	1800-1950	1600	"	1600	Slowly	15-60	1450-1500	"	1-4

^aAfter forging cool slowly in lime or mica.

^bThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^cCooling rate of 50° max. per hr. to 1000°F.

Table III
Heat Treatments for Chisels

Steel No.	Rate of Heating For Hardening	Hardening Temp. °F.	Time at Heat	Quenching Medium	Tempering Temp. °F.
1		1450-1500		Brine or Water	300-550
2		1450-1500		Brine or Water	300-550
3	Slowly and Uniformly	1425-1450	1-4 hr.		
4	Slowly to 1400°F.	1450-1500	10 min.	Brine or Water	350-550
5	Slowly to 1400°F.	1650-1750	10-30 min.	Oil	350-650
6	Slowly to 1400°F.	1650-1750	10-30 min.	Oil	500-650
7	Slowly	1575-1675	10-30 min.	Brine or Water	350-700

Note—With pneumatic chisels various hardening methods are followed to put the shank in proper condition. Sometimes the chisel is treated as above and sometimes the shank is given a preliminary quench in oil from the temperatures given in Table III, after which the cutting edge is hardened as given in Table III, and the whole chisel tempered at the temperatures given.

Shank breakage can be minimized by quenching the tool all over and tempering the shank to a Brinell hardness of 450-500 for steels 1-4 and to 375-430 for steels 5-7.

Thumbnail cracks indicate that the steel was forged too cold. Fatigue failures can be minimized by eliminating decarburized surfaces and tool marks.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stots, Chairman; A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadle, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Composition and Heat Treatment of Cold Striking Dies for Silverware*

(See Also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the process to be followed in the heat treatment of cold striking dies for silverware when they are of the composition given in Table I. The base metal to be stamped may be steel, nickel-silver, or sterling silver.

During hubbing, steel work hardens to such an extent that it must be softened before the hubbing operations can be continued. To soften, the steel is packed and heated to 1250-1300°F., followed by slow cooling.

Table I
Approximate Composition of Striking Dies for Silverware*

Steel No.	C	Mn	V
1	0.90	0.30	0.20
2	1.10	0.30	0.20 Opt.

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Forging, Normalizing and Annealing—The temperatures for forging, normalizing, and annealing are given in Table II.

Table II
Forging, Normalizing, and Annealing Cold Striking Dies for Silverware

Steel No.	Forging ^a			Normalizing After Forging ^b			Annealing ^b		
	Start °F.	Do not Forge Below °F	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1	1800-2000	1500	Slowly to 1450	1600	Slowly to 1450	15-60	1360-1400	Slowly and Uniformly	1-4
2	1800-2000	1500	Slowly to 1450	1550-1650	Slowly to 1450	15-60	1400-1440	Slowly and Uniformly	1-4

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bCooling rate of 50° max. per hr. to 1000°F.

Hardening—To prevent scale from forming in the patterns, the dies are packed in suitable carbonaceous material. Great care should be employed in heating slowly to the hardening temperatures given in Table III. These temperatures are all well above the critical range, because experience has shown that such high heats produce materially better dies.

Table III
Heat Treatments for Cold Striking Dies for Silverware

Steel No.	Rate of Heating For Hardening	Hardening ^a Temp. °F.	Quenching Medium	Tempering ^b Temp. °F.
1	Slowly and Uniformly	1450-1500	Brine or Water	300-550
2	Slowly and Uniformly	1400-1500	Brine or Water	300-550

*When hardening, pack all dies in suitable carbonaceous material or place face down in a pan of carbonaceous material.

^bThe tempering temperature is governed largely by the metal to be worked and the pattern.

To obtain full and uniform hardness, the use of jets or sprays against the impression is recommended. Satisfactory dies can be obtained only by precise control of all operations.

Tempering—After quenching, the dies are tempered immediately at the tempering temperatures given in Table III. The hardness employed depends upon the metal to be struck and the pattern.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stots, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerasen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, P. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Composition and Heat Treatment of Dies for Die Casting*

(See also the General Heat Treatment Article for Tool Steels, Page 987.)

Introduction—A die casting is made by forcing a molten or semimolten metal or alloy under pressure into a metallic mold or die. Little or no machining other than drilling for screws, bolts, and the removal of fins by dressing is required to put the casting in condition for use.

The essential feature in the die casting process which distinguishes it from other processes involving metallic molds, is that the fluid metal is forced into the die cavity by pressure. The pressure may be mechanical, as a plunger working in a cylinder, or air pressure.

Die castings are produced commercially from lead, tin, zinc, aluminum, magnesium, and copper-base alloys. Detailed information on the metals used for die castings will be found elsewhere in this Handbook.

General—Table I lists the steels generally used for die casting dies, with the treatments suggested for them, although it is recognized that other steels may be used.

The composition and heat treatment of steels used in die casting dies depend on the operating temperature. In dies for zinc and lead-base alloys (relatively low temperature work) carbon steels may be used without heat treatment. Aluminum and magnesium-base alloys require heat treated alloy steels; copper alloys (brass) require special steels and heat treatment. For die casting of zinc alloys, high grade "machinery steel" may be used, but certain low alloy steels are preferable, and for longest service the latter should be heat treated. Nitralloy is also used for zinc-base alloys.

Table I
Approximate Composition of Steels for Dies for Die Casting*

Steel No	C	Mn	Si	W	Cr	V	Mo	Ni
1	0.20-0.50							
	Used for Zn, Sn, and Pb base alloys—not heat treated.							
1A	0.50	0.80			0.90			
	Used for Zn, Sn, and Pb base alloys—used as normalized.							
2	0.45	0.70			0.80			1.25
	Used for Zn, Sn, and Pb base alloys—not heat treated for Pb and Sn, but sometimes heat treated for Zn.							
3	0.30	0.50			1.20		0.50 max.	Al-1.20
	Used for Zn, Pb base alloys—preferably in nitrided condition.							
4	0.45	0.60			2.25	0.20 Opt.		
	Used for some long run dies on Zn. Becoming obsolete for Al and Mg Heat treated.							
5	0.35		0.90	4.50	5.25	0.25 Opt.	0.50 Opt.	0.50 Opt.
	Used heat treated—used for Al and Mg base alloys but is giving way to No. 6 and No. 7. Co-0.50 Opt.							
6	0.30	0.60	0.90		5.00	0.25 Opt.	1.00	
	Used for Al and Mg base alloys—heat treated.							
7	0.30		0.90	1.00	5.00	0.25 Opt.	1.00	Co-0.50 Opt.
	Used for Al and Mg base alloys—heat treated.							
8	0.35			10.00	3.00	0.50		
	Used for Cu base alloys—heat treated.							

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Chemical Composition—The approximate chemical compositions of the steels generally used for die casting dies are given in Table I.

Normalizing and Annealing—Die casting die steels as received from the steel mills should be ready for machining. In case further forging must be done the steels should be annealed or normalized and annealed as recommended in Table II. Steels 4, 5, 6, 7, and 8 must be cooled slowly from forging by burying in lime, mica, ashes or similar heat insulating products to avoid strain cracks. Proper normalizing and annealing of these steels should follow this cooling process.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stots, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Table II
Forging, Normalizing and Annealing for Dies for Die Castings

^aAfter forging cool slowly in lime or mica.

^bInstead of annealing, this steel is usually oil quenched from about 1750°F. and tempered at 1250-1350°F. This gives a Brinell hardness of approximately 200-250.

^cThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^dCooling rate of 50° max. per hr. to 1000°F.

^aAfter forging cool slowly in lime or mica.

Instead of annealing, this steel is usually oil quenched from about 1750°F. and tempered at 1250-1350°F. This gives a Brinell hardness of approximately 200-250.

^cThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^dCooling rate of 50° max. per hr. to 1000°F.

Packing for Hardening—It is usually desirable to pack harden dies which require temperatures above 1650°F. in order to prevent excessive scaling. Many die failures are caused from carburized or decarburized surfaces resulting from use of improper packing compounds. Carburization is probably the most dangerous and common result since carbonaceous materials are generally used.

Gray cast iron chips when new are carburizing in action at temperatures above 1650°F., but this action diminishes with use. Partially spent chips may be used at 1650-1700°F. Large, clean chips are preferable.

Aluminum oxide grain of 8-12 mesh size, has been tested and found safe for temperatures between 1750 and 2050°F. At the higher temperature a slight scale may form with this material which is usually not difficult to remove.

Pitch coke, 6-8 mesh size is highly satisfactory when properly prepared. It should first be placed in a pipe or box and heated to 2000°F. until all volatile matter has been removed. Double heating is recommended when high temperature packing is involved. This material has been used from 1700-2100°F. with safety. Below 1700°F. spent pitch coke is decarburizing in action.

In all cases the packing box should be well sealed to prevent access of furnace gases.

Rate of Heating for Hardening and Tempering—It should be remembered that the slower the heating the less the warping or change of size or shape. Therefore dies should not be heated faster than a rate that will give a total heating time of 1½ hr. per in. of greatest thickness of die plus packing material. Frequently it is necessary to heat more slowly than this, to hold distortion at a minimum.

Hardening and Tempering—Table III gives the temperature for hardening and tempering die casting dies. Dies should be tempered immediately after quenching. Tempering furnaces should be at approximately the temperature of the dies being put into them, to prevent too rapid or uneven heating. Dies should not be quenched from the tempering heat.

Tempering temperatures are generally regulated to produce a certain Brinell hardness which experience has shown to give the best results. Dies are frequently tempered on the low side of the range, the hardness tested, and then retempered at a slightly higher temperature if necessary, to produce the desired hardness. This method eliminates the chance of over tempering.

Table III
Heat Treatments for Dies for Die Casting

Steel No.	Preheat Temp., °F.	Rate of Heating for Hardening	Hardening Temp., °F.	Time at Heat	Quenching Medium ^c	Tempering ^{b,d} Temp., °F.
1		Not hardened				
1A		Not hardened				
2		1½ hr. per in. thickness ^a	1500-1550	1 hr./in.	Oil	500-800
3		See the article in this Handbook for instructions on nitriding.				
4			1600-1650 ^a		Oil	800-900
5		1½ hr. per in. thickness	1850-1950	1½ hr./in.	Still Air	1000-1100
6		1½ hr. per in. thickness	1800-1850	1½ hr./in.	Still Air	1000-1100
7		1½ hr. per in. thickness	1800-1850	1½ hr./in.	Still Air	1000-1100
8	1500-1650	Rapidly from Preheat similar to high speed	1850-2150	Do not soak	Air or Oil	1000-1250

^aUsually not treated when used for tin and lead. For zinc, treated dies last longer.

^bDies made from steels 4-8 are used at a working hardness of 402-460 Brinell.

^cDies quenched in oil should not be allowed to become completely cold in the oil. It is necessary to use judgment gained from experience to determine when to remove.

^dThe time at the tempering heat is 2 hr. per in. of greatest thickness, or even longer.

^eFor intricate dies, hold at this temperature for the full specified time, then drop the furnace temperature with the work to 1500°F. Hold until uniform, then quench as above.

Notes About the Process—When die casting aluminum or copper-base alloy castings, first heat the dies uniformly to a temperature of approximately 350°F. Dies for die casting may be given a protective coating before going into service. This coating depends upon the alloy being cast.

Composition and Heat Treatment of Cold Heading Dies*

(See also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the process to be followed in the heat treatment of cold heading dies for steels shown in Table I.

Table I
Approximate Composition of Steels for Cold Heading Dies^a

Steel No.	C	Mn	Cr	V
1	0.90	0.30	0.30 Max. Opt.	0.50 Max. Opt.
2	1.10	0.30	0.30 Max. Opt.	0.30 Max. Opt.

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Annealing for Strain Relieving—Dies and hammers that are cold hubbed should be heated to 1250-1350°F. and slowly cooled before hardening. If much metal is moved in hubbing, alternate annealing and hubbing operations are necessary.

Normalizing After Forging—If normalizing is necessary it should be done according to instructions in the article for the Heat Treatment of Carbon Tool Steel, page 991, and as given in Table II.

Table II
Forging, Normalizing, and Annealing Cold Heading Dies

Steel No.	Forging ^a			Normalizing After Forging ^c			Annealing ^b		
	Start °F.	Do Not Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1	1800-2000	1500	Slowly to 1450	1600	Slowly to 1450	15-60	1360-1400	Slowly and Uniformly	1-4
2	1800-2000	1500	Slowly to 1450	1650	Slowly to 1450	15-60	1400-1440	Slowly and Uniformly	1-4

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bCooling rate of 50° max. per hr. to 1000°F.

Preheating and Hardening—In order to insure thorough heating and to lessen the time required in the hardening furnace, preheating is often advantageous. Preheating and hardening temperatures are shown in Table III.

Table III
Heat Treatments for Cold Heading Dies

Steel No.	Preheat Temp., °F.	Rate of Heating for Hardening	Hardening Temp., °F.	Quenching Medium	Tempering Temp., °F.
1	1000	Slowly and Uniformly	1500-1650 ^a	Brine or Water ^b	300-550
2	1000	"	1450-1600 ^a		300-550

*The size, shape and character of the impression will determine whether the high or low temperature is better for the die.

^bWhen quenching open dies without a jig, brine is preferable to water.

Tempering—Tempering should be started immediately after quenching. Time at temperature should not be less than one hour and longer periods are advisable.

The tempering temperature is governed by the type of die and the material to be headed. For extrusion dies, a minimum Rockwell hardness of C59 is usually necessary.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerasen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Notes on Process—If difficulty from decarburized surfaces is experienced a light coating of boric acid during the heating period may be beneficial in overcoming the trouble. This coating is applied by quickly dipping the preheated die in a hot, saturated solution or by sprinkling the powder on the preheated die.

When hardening solid dies and hammers with deep impressions, it is essential to quench in a jig that forces the coolant, under pressure, into the impression or through the hole in such a way that the forming of all gas pockets is avoided and plenty of fresh coolant impinges against the surfaces to be hardened.

Solid dies of relatively small cross section are usually quenched through the hole only. Large dies may be immersed in the quenching solution while the coolant is forced under pressure through the hole.

When hardening open dies care must be taken to avoid gas pockets in the die impressions. This is best done by a jig that forces the quenching medium against the surface to be hardened.

In hardening heading dies it is essential that a uniform and sufficient depth of hardness be obtained to resist the tremendous pressures developed in the heading operation.

Composition and Heat Treatment of Roll Threading Dies*

(See also General Heat Treatment of Tool Steels, Page 987.)

General—This article covers the heat treatment of roll threading dies made from steels of the approximate compositions shown in Table I. In special cases steels of other compositions may be used but their treatment is not covered by this article.

Table I
Approximate Composition for Roll Threading Dies*

Steel No.	C	Mn	W	Cr	V	Mo
1	1.10					
2	1.10				0.20 Opt.

^aAfter forging cool slowly in lime or mica.

^bThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^cCooling rate 50° max. per hr. to 1000°F.

Forging and Heat Treatments Are Given in Tables II and III

In preparing the hot rolled annealed bars for the milling operation, it is essential that sufficient stock should be machined off to insure the removal of all surface defects and traces of decarburization. The steel must be of uniform hardness to prevent injury to the expensive milling hobs. After the thread form has been milled on the die face, all traces of oil and chips should be removed from the die before hardening.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheidt, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Strain Relieving—After machining a strain relieving anneal at 1100-1200°F. is often beneficial in preventing distortion in the teeth during subsequent heat treatment.

Hardening—In order to minimize distortion it is essential to heat all thread rolling dies slowly throughout the heating cycle. Remove from the quenching bath when the die temperature is reduced, to approximately 200°F. and transfer immediately to the tempering furnace.

Dies made from steels No. 6 and 7 are usually pack hardened or heated in atmosphere controlled furnaces to prevent decarburization. Pitch coke which has been heated to approximately 2000°F. to remove all volatile matter, or cast iron chips, may be used for the packing medium. The box should be heated slowly to 1250-1300°F. and held until a uniform temperature is reached throughout the box. The temperature should then be raised gradually to 1800-1825°F., and held until uniformity is reached in the charge. Remove the dies from the pack, brush free from adhering particles and air cool to room temperature.

Dies made from steel No. 8 are heated in a salt bath, controlled atmosphere furnace, or in a pack of pitch coke. This is necessary to preserve the thread form. In either case a hardening temperature lower than the optimum for 18-4-1 high speed steel when used as a cutting tool is recommended. Dies (steel No. 8) pack hardened in pitch coke should be heated slowly to 1450-1500°F. The container should then be transferred to a furnace heated to 2000-2050°F. As soon as the contents of the pot reaches this temperature the dies should be removed from the pack and oil quenched.

Tempering—Dies should be heated slowly to the temperature shown in Table III and held at temperature a minimum of two hours. Longer tempering times are advisable.

In general, a Rockwell hardness of C 57-59 is satisfactory.

Table III
Heat Treatments for Roll Threading Dies

Steel No.	Preheat Temp., °F	Rate of Heating for Hardening	Hardening Temp., °F.	Time at Heat	Quenching Medium	Tempering Temp., °F.
1		Slowly and Uniformly	1400-1475	15 min.	Brine or Water	300-550
2			1400-1500 ^b	15 min.	Brine or Water	300-550
3		Slowly to 1200	1450-1500	½ hr. for max. Hardness ^a	Oil	325-500

6	1500	Very Slowly	1775-1825	15-45 min.	Oil	400-1000
7	1500	Very Slowly	1700-1800	15-45 min.	Oil	400-1000
8	1450-1600		2250-2350		Oil, Air or Molten Bath	1025-1150

^aDo not soak for minimum distortion.

^bThe carbon-vanadium type can be hardened from a higher temperature than the carbon steels.

Composition and Heat Treatment of Hot Forging Machine Tools*

(See Also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the procedure to be followed for the heat treatment of forging machine tools for hot work when of the composition given in Table I. It is not implied that these are the only suitable steels, but other steels may require different heat treatments.

Steel No. 1 is usually purchased in the heat treated condition and is machined

Table I
Approximate Composition of Hot Forging Machine Tools^a

Steel No.	Purpose	C	Mn	Si	W	Cr	V	Mo	Ni
1	Gripper dies, headers, piercers.....	0.60	0.80			0.75		0.25	1.50
2	Gripper dies, solid dies.....	0.60	0.65			0.90		0.75	2.00
3	Gripper dies, crowners; cut-offs.....	0.90				4.00			
4	Gripper dies	0.60				4.00		0.50	
5	Gripper dies, inserts, piercers,* punches,* headers	0.35		1.00	Opt.	5.00	0.40	1.40	
6	Gripper dies, header dies, solid dies, inserts, punches,* piercers*.....	0.35			10	3.00	0.50

9	Header dies, solid dies, inserts, piercers*	0.50			2.00	1.25	0.25		
10	Gripper dies, headers, solid dies, inserts	0.40	0.60	1.50	7.50	7.50			
11	Punches,* nut dies.....	0.50			18	4.00	1.00	Opt.	

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

*The words "punch" and "piercer" are often used interchangeably. In this article the word "punch" is applied to a tool that punches out a slug, thereby lessening the weight of the forging, whereas a piercer makes a hole without removing any metal from the forging and so not changing its weight.

Table II

^aFor low temperature work.

^bFor high temperature work.

Hardening—With Steel No. 5 heat as specified in the article for high speed steel on page 1000, but to the temperature recommended in Table III, and quench as soon as uniformly heated. All other steels should be heated slowly and uniformly throughout to the hardening temperature specified, and quenched when complete uniformity of heating is obtained.

Tempering—Heat slowly and uniformly to the temperatures given, holding at heat a minimum of 1 hr. per in. of thickness.

Composition and Heat Treatment of Die Blocks and Inserts*

(See also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the process to be followed in the heat treatment of die blocks and die inserts, such as are generally used in forging hammers.

To avoid annealing and rehardening of the dies after each operating service, many users purchase die blocks in the heat treated condition. This applies particularly to the larger sizes. Such dies are usually furnished with a uniformity of five points of scleroscope hardness, and in the hardness range of 40-60 scleroscope. Generally, the shallower the impression, the greater the hardness.

Composition—The approximate chemical compositions of carbon and alloy steel die blocks generally used are given in Table I.

Table I
Approximate Chemical Composition of Die Blocks*

Steel No.	Purpose	C	Mn	Cr	V	Mo	Ni
1	Hot forging	0.60	0.70				
2	Hot forging	0.70			0.25 Opt.		
3	Cold forging	0.85					
4	Drop hammer	0.60	0.70	1.00	Opt.		1.50
5	Drop hammer	0.60	0.70	0.90		0.20	
6	Drop hammer	0.60	0.80	0.75		0.25	1.50
7	Drop hammer	0.60	0.70	1.15	0.15	0.50	
8	Drop hammer	0.60	0.60	0.90	Opt.	0.70	1.75

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Annealing—The die blocks should be heated slowly and uniformly to the annealing temperature given in Table II.

Table II
Forging, Normalizing, and Annealing Die Blocks

Steel No.	Forging*			Normalizing After Forging			Annealing		
	Start °F.	Do not Forge Below °F.	Rate of Heat-ing	°F.	Rate of Heat-ing	Time at Heat, min.	Temp. °F.	Rate of Heat-ing	Time at Heat, hr.
1	1800-2000	1500	Slowly to 1450				1400-1450	Slowly and Uniformly	1-4
2	" "	"	"	1500-1600	1450	15-60	1360-1400	"	"
3	" "	"	"	1600	"	"	"	"	"
4	1850-1950	"	"	"	"	"	1400-1425	"	"
5	" "	1550	"	"	"	"	"	"	"
6	" "	"	"	1600	"	"	1400-1450	"	"
7	1900-2000	"	"	1650	"	"	1400-1425	Slowly and Uniformly	"
8	1850-1950	"	"	1600	"	"	"	"	"

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

Hardening—The die blocks should be warmed in front of the furnace to remove the chill, then charged into the furnace at not over 500°F. The heating time for hardening should be approximately 1 hr. for each in. of diameter or thickness and the time for holding at heat 1/5 for carbon and 2/5 for alloy steels of the time required to reach the hardening temperature. The hardening temperatures are given in Table III.

Carbon steel die blocks are quenched in water (not below 60°F.) and should be immersed face down to a depth of approximately 1 in. below the deepest impression.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stoltz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Rowley, H. A. Anderson and S. C. Spalding.

Table III
Heat Treatments for Die Blocks

Steel No.	Hardening Temp. °F.	Quenching Medium	Tempering Temp. °F.	Scleroscope Hardness	Brinell Hardness No.
1	1425-1475	Water	500-1000	50-70	352-512
2	1475-1525	"	"	"	"
3	1425-1500	"	350-600	70-80	512-600
4	1475-1550	Oil	600-1100	50-73	352-534
5	1475-1550	"	"	"	"
6	1475-1550	"	"	"	"
7	1500-1575	"	"	"	"
8	1575-1650	Air	"	"	"
	1500-1575	Oil	"	"	"

To develop full hardness a geyser of ample volume should be directed against the center of the die impression. Cool down to a temperature of approximately 450°F. or where reheating from the inside is not likely to occur to a sufficient degree to cause softening.

Die blocks that require oil quenching should be completely immersed, with the oil circulating well to give maximum heat dissipation. The volume of the oil bath should be ample so as to avoid an excessive rise in temperature. In case of large dies a strong oil geyser should be directed toward the center of the impression to obtain a uniform high hardness. The dies should be held beneath the surface of the oil until the steel has reached a temperature of approximately 450°F.

Tempering—After quenching the die blocks are tempered immediately at a temperature depending on the final hardness desired (Table III). Tempering may be done by placing the blocks shank down on a hot plate or in a furnace or bath. Blocks or inserts should not be charged in a furnace which is in excess of 400°F. or in a bath which is above 300°F. The heating time to temperature should not be less than 1 hr. per in. of least diameter or thickness and the holding time not less than 2/5 of the total heating time.

The approximate hardness to be expected with 0.60% carbon die blocks after tempering is as follows:

Tempering Temp., °F.	Scleroscope Hardness	Brinell Hardness No.
600	68	493
700	62	444
800	55	388
900	50	341
1000	43	285

Alloy steel die blocks maintain their hardness after tempering better than carbon steel and after tempering will test about 8 points scleroscope higher.

Die blocks for hot forging are rarely tempered below 600°F. Those used for cold work are tempered at lower temperatures, usually 350-600°F. as greater hardness is required.

Die Block Inserts—The term "insert" may refer to a die block (similar in composition and heat treated as such) used to form the entire forging. It frequently has less thickness than a regular die block because it is held in a die block holder. On the other hand, inserts usually refer to the small sections set into a die block in order to strengthen or minimize the wear at one or more points in the die block impression. These are generally made from a more expensive hot die steel and will last as long as the other portions of the impression, thus materially improving the life of the die block.

While hot die steel inserts may be made from a variety of types the more common steels are listed in Table IV and the heat treatments in Table V and VI.

Table IV
Approximate Composition of Hot Die Steels for Inserts*

Steel No.	C	W	Cr	V	Mo
1	0.50	2.00	1.25	0.25	
2	0.35	10	3.00	0.50	
3	0.50	18	4.00	1.00	Opt.

See footnote * in Table I.

^aFor low temperature work.

^bFor high temperature work.

Notes About the Process

Protection of Surface of Die Blocks When Heating for Hardening—In order to reduce scale and decarburization it is recommended that dies be heated in a controlled atmosphere furnace or with the impression face packed in charcoal or spent pitch coke, Fig. 1.

Quenching—When quenching in water it is important not to allow the blocks to cool down too far. The temperature of approximately 450°F. may be determined by holding the head of a household match against the impression face of the block, which should not ignite the match for at least 15-20 sec. Instant ignition will indicate a temperature above 450°F.

To prevent warpage when quenching in water, the shank may be cooled to a black heat by pouring water on it.

When quenching in oil the blocks should be cooled to a temperature of 450°F. If the oil covering the block bursts into a voluminous yellow flame when the block is withdrawn the temperature of the block is too high and it must again be immersed until repeated trials give a blue flame slightly tinged with yellow.

When blocks or inserts are hardened in air, the blast should be dry and so directed as to strike the impression face uniformly. An air pressure of 12-24 oz. is suggested, with ample volume.

Tempering—Large carbon steel die blocks are sometimes tempered on a hot plate. When this method is used the die is placed shank down on a hot plate and heated until the desired color or scleroscopic hardness is obtained on the face. When testing the scleroscope hardness of a hot block it will read 4 or 5 points lower than if tested at room temperature. When relying upon temper color for hardness the following is suggested as a guide: Faint straw, 400°F.; straw, 440°F.; deep straw, 475°F.; bronze, 520°F.; peacock, 540°F.; full blue, 590°F.; light blue, 640°F.

Fig. 1—Method of protecting surface of die block when heating for hardening.

Composition and Heat Treatment of Press Tools for Shearing, Blanking, and Punching*

(See also the General Heat Treatment Article on Tool Steels, Page 987.)

General—This article covers the heat treatment of blanking dies and punches when made from steels listed in Table I. Other steels less common than these may be used in practice, but they may have different heat treatments.

Table I
Approximate Chemical Composition^b

Steel No.	Purpose	C	Mn	Si	W	Cr	V	Mo
1	Cold work, dies and punches	0.85					Opt.	
2	Cold work, dies and punches	1.10					Opt.	
3	Cold work, dies and punches	0.90	1.10		0.50	0.50	0.20 Opt.	
4	Cold work, dies and punches	0.90	1.60

			1700-1800	15-45 min.	Oil	400-1000

^aTo obtain max. hardness hold at heat up to ½ hr. For minimum change in dimension do not hold at heat.

^bHeat treatment for cold work.

^cHeat treatment for pack hardening. Burned pitch coke has been found best adapted for the packing material. Carburizing compounds should not be used. Care must be used in this process that the steel does not become too highly carburized. Too high a carbon concentration on the surface will cause spalling or even an actual fusion of the surface of the die during hardening. Do not hold longer than is necessary to assure that the die has reached the desired temperature.

Notes About the Process—In most cases both the punch and the die are made from the same steel. For dies of intricate design or when distortion is a factor, an air or oil hardening steel should be used, but for more simple designs a water hardening steel may be used.

Preheating of steels 3 and 4 may be done without the use of two furnaces by heating slowly and uniformly to 1200°F. and then heating more rapidly to the hardening temperature. A slow and uniform preheating is helpful in preventing distortion.

Where pack hardening is suggested refer for instructions to the general article on the Heat Treatment of Tool Steels in this Handbook.

Steels 12 and 13 absorb heat at a slower rate than the other steels. They should therefore be heated much more slowly. These steels are sometimes pack hardened, especially if the die will not permit grinding.

Composition and Heat Treatment of Solid Shear Blades*

(See also the General Heat Treatment for Tool Steels, Page 987.)

General—This article covers the heat treatment of solid shear blades and the steels most generally used for hot and cold shearing.

Chemical Composition—The approximate chemical composition of the steels generally used for solid shear blades is given in Table I.

Table I
Approximate Chemical Composition^a

Steel No.	Purpose	C	Mn	Si	W	Cr	V	Mo
1	Cold shearing heavy material	0.85					0.30 Opt.	
2 ^b	Cold shearing light and medium material	1.00	0.35				0.30 Opt.	
3	Cold shearing heavy and medium material	0.55	0.80	2.00		0.50 Opt. (max.)	0.25 Opt. (max.)	0.30 Opt. (max.)
4	Cold shearing light material	0.50	0.40	1.00				0.50
5	Cold shearing heavy and medium material	0.70	0.30			0.90	0.20	
6	Hot and cold shearing of medium or heavy material	0.60	0.60			1.00	Opt.	0.50
7	Warm or cold shearing of medium or heavy material	0.50			2.00	1.25	0.25	Ni 1.50
8	Hot shearing	0.35			10.00	3.00	0.50	
9	Cold shearing light material	0.70			18.00	4.00	1.00	
10 ^a	Cold shearing light material	2.10				12.00	1.00	
11 ^a	Cold shearing light and medium material	1.50				12.00		0.75

^aSteels 10 and 11 may contain optional amounts of V, Ni or Co. With lower carbon content steel No. 11 can be used for hot shearing up to red temperatures.

^bLight shearing means stock up to ¼ in. in dia. or thickness; medium shearing over ¼-¾ in.; and heavy shearing, over ¾ in.

^cThe analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Forging—Heat slowly and uniformly to the temperatures given in Table II. The higher range of temperature refers to large masses subject to heavy reductions and the lower range refers to small masses or light reductions. Forging should be finished as near to but not under the limit indicated. Intermediate or highly alloyed steels should be given retarded cooling after forging, preferably by covering with lime or mica.

Normalizing—For most grades normalizing from the temperatures shown in Table II is recommended.

Annealing—After forging and normalizing, or when resizing a finished blade, heat the steel thoroughly to the temperatures shown in Table II. Soak at heat from 1-4 hr. and cool slowly in the furnace.

Hardening—Heat slowly and uniformly to the temperatures shown in Table III. Quench as directed.

When quenching heavy and long shear blades, it is recommended that the bath be agitated and that the knives be quenched with the edge down rather than the flat and that the knife be turned over during the quench to minimize warpage.

Tempering—Use the temperatures given in Table III. In general it is best to hold at the tempering heat for a minimum of 2 hr. The hardness of the shear

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stetz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, F. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. F. Howley, H. A. Anderson and S. C. Spalding.

blades is governed by the type of material to be sheared and the character of the work to which the shears are to be subjected. For shearing thin material, the scleroscope hardness should be on the high side.

Notes About the Process—Shear blades should be straightened, when quenching, on the descending heat. A straightening machine, such as a hydraulic press, with knife edge supports, should be available in order to apply a quick uniform pressure

Table II
Forging, Normalizing and Annealing of Solid Shear Blades

Steel No.	Forging ^a			Normalizing After Forging			Annealing ^c		
	Start °F.	Do Not Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.
1	1800-2000	1500	Slowly to 1450°F.	1800	Slowly to 1450	15-60	1360-1400	Slowly and Uniformly	1-4
2	1800-2000	1500	Slowly to 1450	1500-1850	Slowly to 1450	15-60	1400-1440	Slowly and Uniformly	1-4
3	1800-1950	1600	Slowly to 1450	1600	Slowly to 1450	15-60	1450-1500	Slowly and Uniformly	1-4
4	1800-1950	1600	Slowly to 1450	1600	Slowly to 1450	15-60	1450-1500	Slowly and Uniformly	1-4

11	1500	Very slowly	1800-1900	15-45 min.	Air	400-1000

^aFor low temperature work. ^bFor high temperature work.

at the desired locations along the knife. For straightening on the descending heat, the shear blades should be withdrawn from the bath at a temperature from 400-600°F., which is just below the point where the oil ceases to flash, or in the case of water quenched blades, just where the water steams or dries off the blades immediately. When it is necessary to straighten after tempering, this should be done as soon as possible while the full tempering heat remains in the shear blade.

Care should be exercised in the selection of an alloy steel for heavy and extra heavy shearing, as deep hardening steels frequently fail by spalling on the cutting edge or by cracking across the blade.

Composition and Heat Treatment of Rivet Sets for Hot Work*

(See also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article deals with two types of rivet dies: (1) Pneumatic rivet sets used in air guns, and (2) compression rivet dies which head by pressure rather than blows. The approximate chemical compositions of the steels generally used for both types of rivet dies are given in Tables I and IV.

Table I
Approximate Chemical Composition for Pneumatic Rivet Sets*

Steel No.	C	Mn	Si	W	Cr	V	Mo
1	0.80	0.35 max.					
2	0.80	0.30				0.20	
3	0.50				0.80	0.20	
4	0.50	0.75		2.00	1.25	0.20	
5	0.55	0.80	2.00		0.50 Opt. (max.)	0.25 Opt. (max.)	0.30 Opt. (max.)
6	0.50	0.40	1.00			Opt.	0.50

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Table II
Forging, Normalizing, and Annealing for Pneumatic Rivet Sets

Steel No.	Forging ^a			Normalizing After Forging			Annealing ^b		
	Start °F.	No Forge Below °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat	Temp. °F.	Rate of Heating	Time at Heat
1	1800-2000	1500	Slowly to 1450	1500-1600	Slowly to 1450	15 min.-1 hr.	1360-1400	Slowly and Uniformly	1-4 hrs
2	1800-2000	1500	Slowly to 1450	1600	Slowly to 1450	15 min.-1 hr.	1360-1400	Slowly and Uniformly	1-4 hrs
3	1800-2000	1500	Slowly to 1450	1650	Slowly to 1450	15 min.-1 hr.	1425-1450	Slowly and Uniformly	1-4 hrs
4	1900-1700			Do not normalize			1450-1475

6	1800-1950	1600	Slowly to 1450	1600	Slowly to 1450	15 min.-1 hr.	1450-1500	Slowly and Uniformly	1-4 hrs

*The temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^bCooling rate 50° max. per hr. to 1000°F.

Table III
Heat Treatments for Pneumatic Rivet Sets

Steel No.	Rate of Heating for Hardening	Hardening Temp. °F.	Time at Heat	Quenching Medium	Tempering Temp. °F.
1	Slowly and Uniformly	1450-1500	15 min.	Brine or Water ^a	300-550
2	Slowly and Uniformly	1450-1500	15 min.	Brine or Water ^a	300-550
3	Slowly and Uniformly	{1425-1450 1550-1600 1650-1750	15 min. 15 min. 15 min.	Brine or Water Oil Oil ^b	300-550 300-550 450-600
4	Slowly and Uniformly	{1550-1600 1550-1650	15 min. 15 min.	Water Water ^c	450-600 600-800
5	Slowly and Uniformly	1525-1575	15 min.	Brine or Water	550-750

^aA 10% brine solution is used.

^bFor this treatment, oil is the preferred quenching medium.

^cIf this steel contains around 0.50% molybdenum, it may be quenched in oil by using a temperature approximately 25-50°F. higher than the temperature for water quenching.

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadle, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

Quenching and Tempering—It is recommended that the rivet sets should be completely immersed while a gentle stream of the quenching medium is being forced into the cup. When quenching, it is good practice to hold the rivet set with a special pair of tongs to keep the water away from the ring, but which at the same time permits uniform cooling of the cup and shank.

The sets should be tempered all over at the temperatures given in Tables III and VI.

Table IV
Approximate Chemical Composition of Steel for Rivet Dies for Hot Pressing^a

Steel No.	C	W	Cr	V
1	0.90		4.00	
2	0.50	2.00	1.25	0.25
3	0.35	10.00	3.00	0.50

^aSee Footnote ^a in Table I.

Table V
Forging and Annealing for Rivet Dies for Hot Pressing

Steel No.	Start °F.	Forging ^b Do not Forge Below °F.	Rate of Heating	Temp. °F.	Annealing ^c Rate of Heating	Time at Heat	Rate of Cooling
1 ^a	1850-1950	1600	Slowly to 1550	1450-1500	1 hr. per in. max. thickness	1-4 hrs.	Max. 50° per hr. to 1000°F.
2 ^a	1850-1950	1550	Slowly to 1450	1450-1500	Slowly and Uniformly	1-4 hrs.	Max. 50° per hr. to 1000°F.
3 ^a	2050-2150	1650	Slowly to 1550	1600-1650	1 hr. per in. max. thickness	1-4 hrs.	Max. 50° per hr. to 1000°F.

^aAfter forging cool slowly in lime or mica.

^bSee footnote ^a in Table II.

^cDo not normalize these steels.

Table VI
Heat Treatments for Rivet Dies for Hot Pressing

Steel No.	Preheat Temp. °F.	Rate of heating for Hardening	Hardening Temp. °F.	Time at Heat	Quenching Medium	Tempering Temp. °F.
1		Slowly and Uniformly	1750-1850	15 min.	Air ^a	950-1100 ^b
2		Slowly to 1400	1650-1750	10-30 min.	Oil	900-1100
3	1500-1550	Rapidly from Preheat similar to high speed	1850-2150	Do not soak	Air or Oil	1000-1250

^aQuench in low pressure air blast or still air.

^bThis tempering range is for dies quenched in air blast. When cooled in still air the dies are usually not tempered.

Composition and Heat Treatment of Taps and Other Thread Cutting Tools*

(See also the General Heat Treatment Article for Tool Steels, Page 987.)

General—This article covers the process to be followed in the heat treatment of taps and other thread cutting tools when made from the steels listed in Table I.

Table I
Approximate Chemical Composition for Taps and Thread Cutting Tools^b

Steel No.	C	Mn	W	Cr	V
1 ^a	1.15	0.30	1.60	0.50	0.20
2	1.15				
3	0.70		18.00	4.00	1.00

^aThis steel is available with optional percentages of Cr or V, either singly or in combination.

^bThe analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

Annealing—Place the steel in the furnace and heat slowly and uniformly to the temperature given in Table II. Hold at temperature for sufficient time to obtain complete penetration of heat. It is recommended that the steel should be protected from furnace gases when heating and cooling. After properly heating, cool slowly in the furnace.

Table II
Forging, Normalizing and Annealing of Taps and Other Thread Cutting Tools

Steel No.	Forging ^a			Normalizing After Forging ^c			Annealing ^a		
	Start °F.	Do Not Forge Below °F.	Rate of Heating	F.	Rate of Heating	Time at Heat, min	Temp. °F.	Rate of Heating	Time at Heat
1	1800-1950	1600	Slowly to 1500	1700	Slowly to 1500	15-60	1450-1475 ^b	Slowly and Uniformly	1-4 hr.
2	1800-2000	1500	Slowly to 1450	1800	Slowly to 1450	15-60	1400-1440	Slowly and Uniformly	1-4 hr.
3 ^c	2050-2150	1700	Slowly to 1600	Do not normalize			1600-1650	1 hr. per in. max. thickness	1-4 hr.

^bIf lead or salt bath is used for heating, cool in lime, mica, or infusorial earth.

^cAfter forging cool slowly in lime or mica.

^dThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

^eCooling rate 50° max. per hr. to 1000°F.

Packing—For instructions on packing refer to the general article on the Heat Treatment of Tool Steels in this Handbook.

Hardening—Steels 1 and 2 are frequently heated in salt or lead baths. When this practice is followed a quenching temperature approximately 25°F. higher than that recommended for furnace heating is necessary. The tools should be preheated before immersion in the bath and should be withdrawn from the quenching medium when cooled to 200°F.

Maintenance of thread form and prevention of excessive lead change is more difficult with tools made from steel No. 3. Controlled atmosphere furnaces or salt baths are beneficial. When using controlled atmosphere furnaces a high CO content with low moisture and CO₂ is suggested. If semimuffle type furnaces are used a large excess of gas should be maintained and the tools removed for quenching as

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stotz, Chairman, A. S. Jameson, A. J. Scheid, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

soon as the temperature in Table III is reached. The operation should be guided by the temperature of the threads.

Tempering—After quenching, reheat immediately in oil, salt, or furnace for the time and temperature specified in Table III.

Table III
Heat Treatments for Taps and Other Thread Cutting Tools

Steel No.	Preheat Temp., °F.	Rate of Heating for Hardening	Hardening Temp., °F.	Quenching Medium	Tempering Temp., °F.
1		Slowly and Uniformly	1575-1625 ^a	Oil	350-550
2		Slowly and Uniformly	1400-1475 ^b	Brine or Water	300-550
3	1450-1600	Slowly and Uniformly	2250-2350 ^c	Oil, Air or Molten Bath	1025-1150

^aIf a lead bath is used for heating, a higher temperature and shorter time at heat may be used.

^bHold shortest time possible to thoroughly heat through.

^cWhen heating in fused salts or controlled atmosphere furnaces, the hardening temperature is generally 2275-2350°F.

Notes About the Process—It is assumed that the tap shanks are below the hardening temperature and are not fully hardened. If the shanks have been fully hardened they must be tempered in order to toughen them, especially the smaller sizes. Acme style threads as well as modified or coarse pitch threads should be tempered at the higher temperatures.

Composition and Heat Treatment of Steels for Plastic Molds*

(See also the General Article on Heat Treatment for Tool Steels, Page 987.)

General—This article covers the steels and their treatments for plastic molds, but may not include all types of steels used for this work.

Plastic materials are those derived from phenol, urea, rubber, casein, and other bases, and are molded in steel molds under pressure and usually with heat. Since the molded article depends upon the character of the cavity in the mold not only for its shape, but for the perfection of its finish as well, it is necessary that mold steels be of high quality with regard to cleanness and response to heat treatment.

The mold cavities are formed either by hubbing or by cutting. The operation of hubbing consists of sinking the impression cold with a master hub. Since die steels which are to be hubbed must be annealed quite soft, they are usually of the carburizing type.

Where the conditions are such that the hubbing steels cannot be used the dies are machine cut.

Requirements of Mold Steels—From the foregoing it is obvious that a good mold steel should have the following properties: 1. Cleanness; 2. Ease of fabrication in hubbing, machining, and heat treating; and 3. Strength to resist deformation in service, and wear resistance.

Cleanness—It is desirable that the steel be free from internal defects which might appear on the surface of the cavity and mar the finish of the product. Under operating pressures and temperatures, these internal defects tend to open and leave ridges or imperfections on the surface of the work. The hot acid etch test as described elsewhere in this Handbook is therefore recommended for the inspection of steel for plastic molds.

Table I
Approximate Composition for Molds and Hubs*

Steel No.	Purpose	C	Mn	W	Cr	Mo	Ni	Annealed, Brinell Hardness, max.
<i>Steels Used for Molding</i>								
1	Hubbing	0.05	0.15					100
2	"	0.10	0.20		0.60		1.25	125
3	Cut die and hubbing	0.15	0.45		1.50		3.50	150
4	"	0.15	0.45			0.30	1.50	150
5	Cut die	0.40	0.45		1.50		3.50	200
6	"	0.90	1.60					200
7	"	0.90	1.10	0.50	0.50			200
8	"	1.50			12.00	0.75		230
<i>Steels Used for Hubs</i>								
9	Hubs*	0.50	0.40		0.80	0.75	1.50	200
10	Hubs	0.90	1.10	0.50	0.50			200
11	"	1.50			12.00	0.75		230

*The analyses given are type analyses only. Actual analyses of the steels they represent will, of course, vary from these averages a reasonable amount. It should be remembered that the greater the variation in analysis of any steel from these averages, the more the treatment may differ from that recommended.

*There are many types of tool steel used for hubs. The steels described here are only meant to be typical examples.

Ease of Fabrication in Hubbing, Machining, and Heat Treating—Some molds are shaped largely by hubbing, some by machining and others by a combination of both. The depth to which a hub can be driven in, as well as the power needed for the operation, depends largely upon the hardness of the mold steel when annealed. This in turn depends upon analysis; a steel containing no alloys can be annealed considerably softer than an alloy steel of the same carbon content. Consequently the easy hubbing steels do not generally make as strong a mold as

*Prepared by the Subcommittee on Tool Steel. The membership of the subcommittee was as follows: N. I. Stoltz, Chairman, A. S. Jameson, A. J. Scheld, Jr., G. V. Luerssen, W. H. Wills, Burns George, J. E. Erb, P. J. McCarthy, F. F. McIntosh, J. H. McCadie, C. L. Harvey, H. T. Cousins, J. A. Succop, A. D. Beeken, Jr., J. P. Howley, H. A. Anderson and S. C. Spalding.

those which are more difficult to hub. The selection of the steel will therefore be a compromise between final strength and wear resistance and hubbing properties.

Easy and clean machining properties are desirable in mold steels that must be machined to shape. Since cleanness is an important factor the high sulphur types are not desirable, and careful annealing must therefore be depended upon to produce the required machining properties.

In heat treating there are three factors which must be carefully watched in addition to the usual requirements, namely distortion, scaling and soft spots. All three are very undesirable.

Strength and Wear Resistance—The question of strength is vital in dies having thin sections, or in large dies where an entire surface may sink under heat and pressure. In the latter instance when a case hardening steel is used, core hardness is of considerable importance.

Wear resistance is of importance on long run dies, and is greatly improved by the addition of alloys.

Steel Compositions and Treatments—Table I shows average analyses of a number of die steels used in plastic molds. Included are several tool steels used in making the hubs. Tables II and III give the heat treatment for these steels. Since it is sometimes necessary in the hubbing of deep impressions to reanneal between operations, this table also covers annealing treatments.

Details of Four Steels—The type of steel selected will depend upon a number of factors involved in the particular application. The entire field can usually be covered by four steels, namely No. 1, 2, 3 and 6 in Table I.

Table II
Forging, Normalizing and Annealing Molds and Hubs

Steel No.	Forging ^b Do not Forge Below			Normalizing After Forging			Annealing			
	Start °F.	Rate of Heating	°F.	Rate of Heating	Time at Heat, min.	Temp. °F.	Rate of Heating	Time at Heat, hr.	Rate of Cooling

8*	1800-1950	1600	Slowly to 1600	Do not normalize		1600-1650	1 hr. per in.	1-4	Max. 50°/hr. to 1000°F.	Slowly
9	1700-2000	1500	Slowly	1550	Slowly	15-60	1425-1450	Slowly and Uniformly	1-4	Max. 50°/hr. to 1000°F.
10	1800-1950	1600	Slowly to 1500	1550	Slowly to 1500	15-60	1400-1425	Slowly and Uniformly	1-4	Max. 50°/hr. to 1000°F.
11*	1800-1950	1600	Slowly to 1600	Do not normalize		1600-1650	1 hr. per in.	1-4	Max. 50°/hr. to 1000°F.	Slowly

*After forging cool slowly in lime or mica.

^bThe temperature at which to start forging is given as a range, the higher side of which should be used for large sections and heavy or rapid reductions, and the lower side for smaller sections and lighter reductions.

Steel No. 1 is suitable for the manufacture of intricately shaped molds where ease of hubbing is of primary importance. It can also be used to advantage where only short runs are needed. Since the steel can be annealed to 100 Brinell it will permit a large amount of hubbing. For the same reason it is somewhat difficult to machine, although the machining properties are considerably improved when severely worked by partial cold hubbing.

Since this steel is a carburizing type with a relatively soft core extremely high pressures are not possible. For short runs, dies may be cyanided rather than carburized.

Steel 2 is a good general purpose mold steel, applicable to the manufacture of practically all classes of molds. While not quite so easy to hub as steel No. 1 still

its hubbing properties can be made satisfactory by proper annealing. It has the advantage of greater core strength, greater case strength, and greater wear resistance. It can be machined without great difficulty and can be hardened uniformly without danger of soft spots when quenched in either brine or oil.

Steel No. 3 (as well as 4) is adapted to the manufacture of large dies and for dies where maximum strength and length of service are required. While this steel is included under the steels for cut dies some hubbing operations are possible. With proper annealing it can be made to machine quite freely. It has the advantage of an extremely high core strength to withstand heavy loads even in large sections without cracking of the mold surface. It is excellent for wear resistance. It is capable of carburizing and heat treatment with no danger of soft spots.

Table III
Heat Treatments for Molds and Hubs

Steel No.	Carburizing °F.	Preheat Temp. °F.	Rate of Heating for Hardening	Hardening Temp. °F.	Time at Heat	Quenching Medium	Tempering Temp. °F.
1	1700		1½ hr. per in.	1450-1475	15 min.	Brine or Water	300-400
2	1700		1½ hr. per in.	1450-1475	15 min.	Brine or Water	300-400
3	1700		1½ hr. per in.	1400-1425	15 min.	Oil	300-400
4	1700		1½ hr. per in.	1400-1425	15 min.	Oil	300-400
5			1½ hr. per in.	1600-1625	15 min.	Air	300-350
6			1½ hr. per in.	1400-1475	Do not soak	Oil	325-500
7			1½ hr. per in.	1450-1500	Soak for hardness up to ½ hr. For min. change don't soak	Oil	325-500
8		1500	1½ hr. per in.	1700-1800	15-45 min.	Oil	400-1000
				1800-1900	15-45 min.	Air	400-1000
9			1½ hr. per in.	1700-1750	15 min.	Oil	400-500
10			1½ hr. per in.	1450-1500	Soak for hardness up to ½ hr. For min. change don't soak	Oil	325-500
11		1500	1½ hr. per in.	1700-1800	15-45 min.	Oil	400-1000
				1800-1900	15-45 min.	Air	400-1000

Steels No. 6 and 7 are used when it is not desirable to carburize. Hubbing is not recommended. Strength and wear resistance are excellent. These steels have the advantage of uniform hardness and freedom from size change in hardening.

Carburizing Introduction

By. R. B. Schenck*

The process now known as carburizing dates back many centuries. The old cementation process in which a material similar to our puddled iron was made to absorb carbon from charcoal without fusion was the sole source of steel at one time. By a sufficiently prolonged exposure small bars of hammered iron were carburized more or less throughout their full cross section resulting in the so-called "blister steel" of that day. Later came the melting of blister steel in crucibles to be followed finally by our modern methods of melting and refining.

As practiced today, the process of carburizing is applied to finished or semi-finished articles of ferrous metal with the object of increasing the carbon content of the surface so that when subjected to suitable heat treatment the surface portions so carburized will be substantially harder than the underlying metal. Thus, a low carbon steel article which in its original condition will harden but little on quenching, can be carburized and then quenched, producing a hard, wear resisting surface and a softer interior. The combined process of carburizing followed by hardening has been long known as "case hardening."

This combination of hard surface and softer interior made possible by case hardening is of inestimable value in modern engineering practice. By the use of alloy steels, great strength and toughness in the core can be combined with extreme surface hardness, resulting in a composite structure capable of withstanding certain kinds of stress to a high degree. For less exacting requirements, there are innumerable applications where low or moderate core properties together with a high degree of surface hardness can be readily obtained with cheaply fabricated, low priced carbon steels.

Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

Carburizing Methods

By R. B. Schenck*

General—Commercial carburizing may be accomplished by any one of the following methods: (1) pack carburizing; (2) gas carburizing; or (3) liquid carburizing.

As implied by the above terminology, the three methods depend respectively upon the action of agents which are solid, gaseous or liquid at the carburizing temperature.

In pack carburizing the work is heated in contact with a solid carburizing compound in a closed container. In the gas method the work is exposed to the action of a carburizing gas in a heated chamber. In liquid carburizing the work is immersed in a fused carburizing salt.

A choice of the method to be used depends upon so many factors that it becomes rather difficult to set up any definite rules to be followed. The design of the part, type and depth of case, permissible distortion, production volume, initial investment and operating cost, must all be taken into consideration and present such an involved picture that the only correct procedure is to judge each individual case on its own merits.

Pack Carburizing—The pack method is the oldest and for years has been the one most extensively employed. In its various modifications it has been used for practically every kind of an article that could be carburized, ranging from type-writer parts to armor plate. It is usually considered the most fool-proof of the three methods, and the safest to use in the absence of trained supervision.

The usual form of the pack method, frequently referred to as "box carburizing," lends itself readily to either batch or continuous furnace operation. The packing material provides an excellent support for pieces which tend to warp in heating and the natural slow cooling in the containers, where direct quenching is not used, tends to hold warpage to a minimum. The outstanding disadvantages are the time consumed in heating the charge, the high labor cost involved in packing and unpacking and the preclusion of automatic quenching.

The only other form of pack carburizing which deserves mention here is the "rotary retort" method, suitable only for batch operation. This modification of the pack method has been in use for many years. Its application is limited to parts which can withstand the necessary tumbling action without injury. The labor cost is low since the work is handled in bulk for both charging and discharging. The charge may be either direct quenched or slowly cooled in a suitable container. Heating is extremely rapid thus materially reducing the time required for a given depth of case. For parts which can withstand the rough handling of this method, it is probably the most economical one yet developed.

Gas Carburizing—Although the gas method of carburizing is not by any means a new one, it has never been used as extensively as its possibilities seem to warrant. However, gas carburizing is now undergoing intensive development and according to present indications may eventually replace other methods to a very large extent.

One of the oldest commercial forms of gas carburizing is the rotary retort method, very similar to the one described under Pack Carburizing but using gas instead of solid material. In general, the same advantages and limitations apply to both. Stationary horizontal and vertical retorts, also limited to batch operation, are used to some extent.

The most noteworthy development has been in equipment for continuous gas carburizing with either automatic quenching, hand quenching, or slow cooling. Labor costs are low, but initial investment is high and large units operated at high output are necessary if full operating economy is to be attained. The controls are rather complicated and the successful operation of these units requires trained supervision.

For work which can be handled in sufficient quantity by the above method, the operating costs can be reduced to a low figure, especially where automatic quenching is employed. Temperature and case depth are extremely flexible. Units

*Chief Metallurgist, Buick Motor Co., Flint, Mich.

Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

are now in operation at 1500°F. producing cases of 0.005 in. on automotive transmission gears. Equally satisfactory operation is being obtained with heavy cased work at temperatures as high as 1800°F.

An important characteristic of gas carburizing is the ease with which the case composition can be controlled. By suitable adjustment of time, temperature and gas composition, the surface carbon and the carbon gradient can be varied to meet almost any requirement. Additional flexibility is available in batch operation by varying the rate of flow and composition of the gas throughout the cycle.

Liquid Carburizing—Progress in the technique of liquid carburizing, both with respect to the carburizing agent and the equipment, has been extremely rapid in the last few years. The new activated baths with their higher rate of penetration and better quality of case, together with improved methods of heating and control, are extensively replacing the old cyanide pot in the more progressive plants. Automatic handling is also being introduced in certain applications with marked success.

Liquid carburizing is used for light cases at moderate temperatures. For case depths of more than about 0.030 in. other methods are employed. The process is extremely flexible, easily controlled and particularly well adapted to small units. With continuous operation and automatic quenching, labor costs can be reduced to a low figure. The largest single item of operating expense is the carburizing salt.

The Mechanism of Carburization

By R. W. Schlumpf*

Sources of Carbon—The carburization of steel is effected by heating it to relatively high temperatures (usually within the range of 1600-1800°F.) in contact with carbon-bearing materials which are capable of yielding carbon to the metal surface. These carburizing materials can be gases, liquids or solids.

The most important carburizing gases are carbon monoxide and hydrocarbons such as methane, ethane, propane and butane, which exist as gases at atmospheric temperature and pressure.

Carbon monoxide is the carburizing agent in the so-called "pack" method of carburizing, where the metal to be carburized is packed in a sealed container with some form of free carbon to which is usually added a metallic carbonate. The metallic carbonate or "energizer" decomposes when heated and yields carbon dioxide gas which in turn reacts with the free carbon in the mixture to form carbon monoxide gas.

The hydrocarbons, methane and ethane, are the principal carburizing agents in the so-called "gas" method of carburizing where either natural or manufactured gas containing relatively high percentages of either or both of these hydrocarbons is brought in contact with the steel at carburizing temperatures. Propane and butane are liquified under pressure for transportation and storage, being converted to the gaseous state preceding their introduction to the high temperature of the carburizing chamber. Hydrocarbons that exist as liquids at atmospheric temperature and pressure are converted to gases when introduced into the high temperature carburizing chamber.

Carburizing liquids are generally defined as chemical salts of the cyanogen radical type that yield carbon by direct or indirect action when heated in contact with the steel. The temperature required for carburizing action is above the melting points of these commercial salt-type carburizing materials, hence these carburizers are used in the liquid state and the process is referred to as liquid carburizing.

Solids have no practical importance as direct carburizers. The solids involved in the important commercial carburizing processes all have an indirect action in that they are only accessory to the generation of the direct-acting carburizing agent. It is generally agreed that steel cannot be carburized in direct contact alone with any of the commonly used forms of free carbon. It has been demonstrated that steels such as S.A.E. 1020 and 3115 show no measurable amount of carburization after heating to a temperature of 1700°F. for several hours in contact with hard-wood charcoal in an atmosphere evacuated to about 5 mm. of mercury. In repeating this test with the vacuum pump disconnected and the container closed with a non-pressure-tight seal a case depth of about 0.060 in. was obtained under the same conditions of time, temperature and carburizing material.

Molecular carbon such as soot that has been formed by the dissociation or decomposition of a carburizing gas is relatively inactive and can become active for carburizing only by recombining with another element to form a carbon compound.

Absorption and Diffusion of Carbon in Steel—All carburizing depends on the ability of the carburizing medium to supply atomic carbon to the metal surface. Whether this atomic carbon passes directly into the space lattice until a saturation value for the existing temperature is reached or whether the carbon atom is conveyed into the metal by a chain of interactions in which iron carbide is first formed at the surface and then, through dissociation, yields carbon to the next group of iron atoms is still controversial. The equations representing the carburizing reactions for two of the common gaseous media may be stated as follows:

The equilibria involving these reactions in the carburization of steel are shown in the diagrams prepared by various investigators.¹⁻¹¹

*Metallurgical Engineer, Hughes Tool Co., Houston, Tex.

Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

Iron carbide can be formed by the reaction of iron with carbon monoxide at temperatures as low as 1150°F. This would indicate that the formation of carbide at the surface of the metal is the first step in the mechanism by which carbon is absorbed. This belief is supported by the fact that at low carburizing temperatures, where the rate of diffusion is low, it is possible to build up a surface carbon content by the continued formation of iron carbide considerably in excess of the saturation value for the austenitic solid solution. When carburizing at 1700°F. it is likely that carbon atoms first saturate the austenitic solid solution with carbon and when supersaturated the austenite precipitates Fe_3C . When carburizing at the low temperature of 1150°F. the ferrite supersaturates in the same way and precipitates Fe_3C .

Diffusion tests at higher temperatures, with the gaseous carburizing medium removed, show that carbon will diffuse inward from this surface carbide. The ability of iron carbide to furnish diffusible carbon is demonstrated by tests where white iron particles were placed in a low carbon steel chamber which was then evacuated to about 5 mm. of mercury, heated to 1700°F., held for several hours and then slowly cooled. After cooling to atmospheric temperature the vacuum pump was disconnected, the steel chamber sectioned and found to be carburized where it had been in contact with the white iron particles. The bottom part of the chamber, in contact with the white iron particles of about 100 mesh size, was carburized to about twice the depth that was observed immediately above where 20-40 mesh particles were placed on top of the 100 mesh layer. The general appearance of the contour of the inner edge of the case indicated that the carburization had taken place by linear diffusion of carbon from each point of contact of a white iron particle. The top part of the chamber above the charge of the iron carbide-bearing particles showed no carburization. This test was repeated with pulverized hardwood charcoal under the same conditions of temperature and pressure and no carburization was observed.

The degree to which the carburizing gas actually penetrates beneath the surface of the steel before liberating atomic carbon or reacting with the steel to form iron carbide is controversial. While there is definite evidence that oxygen as well as carbon is released for diffusion into the steel when carburizing with carbon monoxide and that hydrogen can diffuse along with the carbon when carburizing with methane, the exact extent to which these carbon-bearing gases might penetrate before decomposing has not been definitely determined. It can only be broadly stated that the extent of penetration would be determined by sub-surface equilibria in the system $\text{CH}_4\text{-C-H}_2\text{-Fe}_3\text{C}$ -austenitic solid solution when carburizing with methane or $\text{CO-C-CO}_2\text{-Fe}_3\text{C}$ -austenitic solid solution when carburizing with carbon monoxide. It has been suggested that the jog usually observed near the surface in carbon gradient curves for the lower carburizing temperatures might indicate the zone of gas penetration and that portion of the curve above the jog represents gas decomposition, carbide formation and carbon diffusion while the curve below the jog represents carbon diffusion only.

Another factor that might play an important part in the mechanism of carbon absorption is the possible metal vapor phase in existence at the surface of the steel. Evidences of this metallic vapor phase or sublimation of the iron have been observed in carburizing with hydrocarbon gases but have not been studied in sufficient detail to identify or definitely establish the authenticity of this factor. Samples of soot from a basket taken from a production methane-carburizing heat were

Fig. 1—Carbon Gradient Curves for S.A.E. Steel 3115. Carburized at 1700°F. in Hardwood Charcoal, Coke, Sodium Carbonate Compound.

found to analyze as high as 30% iron. The iron was apparently thoroughly distributed throughout the soot and was not confined to layers immediately in contact with the surface of the steel that had been carburized. Evidences of a metallic vapor phase have been found in heating other metals in the presence of hydrogen in a sealed container to temperatures well below the melting point. While it is possible that this metallic vapor phase might be a volatile metallic compound rather than the true vapor phase of the metal we cannot neglect to consider that it would be expected to be a very active intermediate agent in the transference of carbon from the carburizing medium to the steel.

Catalysis is still another factor that is evident in carburization but not thoroughly understood. It has been proposed that the metallic oxide resulting from the decomposition of a metallic carbonate energizer in the commercial pack carburizing compound acts as a catalyst in the $\text{CO}_2 + \text{C} \rightarrow 2\text{CO}$ reaction.¹³ This is supported by the observation that the oxide when used alone as an energizer is effective. There are evidences that the surface of the steel being carburized and the walls of the container have a catalytic effect on the reactions involved in carburizing. It has been noted that under the same conditions of temperature, gas flow and pressure in a carburizing process with methane that different types of metals used for the container or fixtures for holding the work will exert different influences toward the deposition of free carbon. The probable catalytic effect of an iron oxide skin produced on the surface of the steel by the introduction of a closely controlled amount of water vapor previous to the introduction of the carburizing gas in a retort type gas carburizing operation has been reported and discussed.¹⁴ The exact mechanism of catalysis in carburizing is still elusive and demands further study.

Under some conditions oxygen-bearing gases present in pack carburizing appear to influence the size of the austenite grains developed in the case and the microstructure of the slowly cooled product (McQuaid Test, page 750).

Mechanism of Cyanide Hardening—The reactions occurring in the cyanide bath are somewhat complicated and more or less hypothetical. Tests made in vacuo indicate that the absence of oxygen prevents carburization. It is therefore generally recognized that the conversion of sodium cyanide to sodium cyanate is an essential step in the process of cyanide hardening.

The accepted chemistry of the process is as indicated:

1. $\text{NaCN} + \text{O} = \text{NaCNO}$
2. $4\text{NaCNO} + \text{heat} = 2\text{NaCN} + \text{Na}_2\text{CO}_3 + \text{CO} + 2\text{N}$
3. $2\text{CO} = \text{CO}_2 + \text{C}$

Sodium carbonate is the ultimate decomposition product of sodium cyanide when operated commercially in a fused bath.

The various activated baths differ in composition. Barium chloride or carbonate are ingredients in several baths. Calcium cyanamid with a calcium and sodium

Fig. 2—Carbon Gradient Curves for S.A.E. Steel 3115. Carburized at different temperatures in same type compound as Fig. 1.

chloride is another type. The chemical reactions are, however, all based upon the employment of the cyanogen radical introduced by a cyanide compound.

The chemistry of a typical activated bath utilizing barium salts may be illustrated as follows:

1. $\text{Ba}(\text{CN})_2 = \text{BaCN}_2 + \text{C}$
2. $\text{BaCN}_2 + \text{Na}_2\text{CO}_3 = \text{BaO} + 2\text{NaCNO}$
3. $4\text{NaCNO} + \text{heat} = 2\text{NaCN} + \text{Na}_2\text{CO}_3 + \text{CO} + 2\text{N}$
4. $2\text{CO} = \text{CO}_2 + \text{C}$

Those containing calcium, where CaO would be formed in the second reaction, produce infusible residues in the bath.

Factors Affecting the Distribution of Carbon in the Case—Regardless of the exact manner in which the carbon becomes a part of the metal, carbon gradient analyses indicate that it diffuses in accordance with the laws of linear diffusion generally definable by a diffusion equation such as Carslaw's equation for linear heat flow.

In the carburizing process the rate of diffusion depends on temperature, carbon concentration gradient, pressure and factor of diffusivity for the particular steel in use. Diffusion rate increases quite rapidly as the temperature increases. The effect of carbon gradient is manifest in the speed with which a low carbon steel can be carburized as compared with a high carbon steel. Pressure is thought to be a factor only in so far as it influences the concentration of active carburizing gas in the surface gas-metal equilibria. The diffusivity factor of the steel is related to its chemistry in so far as the elements other than iron and carbon are concerned. It has been generally observed that those alloy elements which are not essentially carbide formers tend to retard the progress of carburization by impeding both the surface carbon build-up and the diffusing action. The elements that are strong carbide formers tend to increase the surface carbon concentration and the speed of carburization.

At temperatures within the usual carburizing range where the steel exists as austenitic or gamma iron solid solution there is the tendency, with high concentration of carburizing agent, for the carbon concentration at the surface of the steel to increase until the saturation value for the austenite (as indicated for any given temperature on the SE line on the iron-carbon diagram) is attained and then continue increasing by the formation of free iron carbide or cementite. The degree to which the carbon can be built up in solution in the austenite or to continue building up by the formation of cementite after the austenite is saturated is indicated in equilibrium diagrams prepared by various investigators, as previously mentioned. While the carbon concentration is building up at the surface the inward diffusion of carbon is in progress. The resulting degree of carbon concentration in successively deeper parts of the case (from the surface to the core) after carburizing at a given temperature therefore depends on the ability of the diffusing action to overcome the tendency to build up the

Fig. 3

Fig. 4

Fig. 4—Same steel and compound as Fig. 3. Carburized 130 hours at 1500°F. and quenched in water from carburizing container. Shows existence of free carbide or cementite at the carburizing temperature. Etched in Picric acid $\times 250$.

carbon at the surface. At the common carburizing temperature of 1700°F. a set of curves showing carbon concentration in S.A.E. 3115 steel in a conventional hardwood charcoal-coke mixture energized with sodium carbonate is given in Fig. 1. It will be noted on these curves that the steep gradients established in the shorter periods of carburization indicate the tendency for rapid build-up of carbon at the surface. With the longer periods of carburization the surface carbon increases only slightly over that observed for the shorter periods of carburization, being continuously depleted by diffusion. At this temperature the balance between carbon build-up and diffusion results in a surface carbon concentration closely approximating the equilibrium value for saturated austenite as indicated on the SE line of the iron-carbon diagram.

If the carburizing temperature is lowered sufficiently the diffusing speed is reduced to the extent that the carbon can build up to values far in excess of the equilibrium value for saturated austenite. This condition is shown in the set of curves (Fig. 2) representing carburization of S.A.E. 3115 steel at different temperatures to approximately the same case depth in the same type of compound as above. The carburizing was sufficiently vigorous throughout the period of carburization to facilitate the saturation of the austenite and then continue the formation of iron carbide. At the lowest temperature on this set of curves (1500°F.) the core still contains alpha iron which further retards diffusion of the carbon. The surface carbon build-up at this low temperature is illustrated in the photomicrographs of Fig. 3 and 4.

While the selection of carburizing temperature for certain jobs, in some instances, might be based on the desire to produce a predetermined carbon gradient in the case, the temperature in the majority of commercial applications has been arrived at through counterbalancing the diffusion rate factor against the effect of the higher temperatures on the physical properties of the steel and on the carburizing equipment.

The relation of time to carbon penetration or case depth is illustrated in the set of curves of Fig. 5 prepared from test runs in a production vertical stationary type gas retort using natural gas at atmospheric pressure. These curves approximate closely the rates obtainable regardless of the medium used.

In the pack carburizing process the carbon gradient in the case can be controlled to a certain extent by the choice of the form of carbon to be used in the compound. If the factors in a pack carburizing operation are fixed as regards compound, temperature, and chemistry of the steel the carbon gradient of the case can be controlled by a diffusing cycle, usually requiring a second or additional operation.

In the gas carburizing process the factor of surface gas-metal equilibria can be more easily manipulated by varying the gas flow rate, introduction of diluents, interruption of gas flow, and variation of chamber pressure, than by varying the temperature, due to the effect of the latter on gaseous equilibria. In the $\text{CH}_4 \rightleftharpoons \text{C} + 2\text{H}_2$ system the active carburizer (CH_4) becomes less stable as the temperature increases while in the $2\text{CO} \rightleftharpoons \text{C} + \text{CO}_2$ system the active carburizer (CO) becomes more stable with increasing temperatures.

Selection of Carburizing Steel, Case Depth, and Heat Treatment

By Gordon T. Williams*

Introduction—A great variety of steel types may be used for the production of case hardened parts having the qualities described later, that is, a hard, wear or fatigue resistant surface on a core of relatively tough, shock-resistant nature, resulting in a part of required durability.

The following two basic factors must be considered first when selecting a steel for use in this process: a. Quenching medium to be used as demanded by sections and distortion limits; b. Type and degree of stresses to which the finished part will be subjected.

Since these are also the factors which will determine the heat treatment to be used, obviously steel and treatment must be simultaneously considered.

The quenching medium to be used is ordinarily rather easily decided. Water or aqueous solutions will be preferred, due to low cost of medium, rapidity of cooling, and ease of subsequent cleaning; such coolants will be used wherever simple shapes or massive sections permit their application. When sections are thin so that cracking or warping is probable, and when accurate contours must be preserved, as in gears, slower media, usually oil, must be used. From such consideration decision can be made as to relative hardenability required and permitted in the steel.

The quenching medium must be selected with regard to attainment of desired hardness of the carburized surface and also in many cases the attainment of required hardness and strength of the core at some depth below the surface. The critical cooling velocity is, of course, the factor here. If maximum surface hardness is the only requirement, steel containing only carbon or low amounts of alloying elements will be selected, to be quenched in water. If, however, too much distortion would result from this quench, or cracking is encountered, then oil will be used, and a steel must be selected having sufficient alloying elements that the lower cooling velocity will still be above the critical rate for the steel.

The type and degree of stresses to which the finished part will be subjected will indicate the physical properties demanded in the core, as well as the preferred metallographic character of the case and its depth. Static compressive loads normal to the surface require only sufficient depth of case and hardness of core that the former does not deform when stressed. A case too shallow or a core too weak will result in surface deformation under the load. This type of failure is often called "brinelling" because of its similarity to the effect of Brinell testing of a hardened case. Abrasion of the case hardened surface will usually be best resisted by a case of maximum hardness, with low contents of austenite to resist flowing under the load, and sufficient depth to give reasonable life in wear. However, wear is of several types, and there are many exceptions to the above statement; type of case must be selected to best resist the specific kind of abrasion encountered.

When bending stresses are encountered, the factors of core hardness and case depth are so directly related that they must be simultaneously considered, as shown by Woodvine. Fig. 1 illustrates the Woodvine' principle. In this diagram, stress in a beam is plotted against distance from the neutral axis, the points along the line OA. The endurance limit of the case is represented by BC, that of the core by DG. The line BPQG thus represents the endurance limit of the case hardened piece. Were the core fatigue limit lower, the point Q would be to the left of the stress line OA, and fatigue failure would occur in the core just below the case. The strength of the over-all part may thus be increased by increasing the core strength (hardness) or by increasing the case depth. Internal stresses may weaken the case but do not add to the strength of the core, so the core is of more importance than theoretical considerations would indicate. Probably due to internal stresses, increase in case depth does not raise the case strength except with certain treatments, as shown by McMullan.²

The combination of case depth and core strength must be sufficient that the stress does not exceed the endurance limit of the material at any given distance from the neutral axis. It must be noted that stress-raisers, such as notches and tool

marks, will make the direct application of this principle ineffective.³ Since the rate of carburization falls off rapidly as greater depths are sought, a more economical method of meeting the stress-resisting requirements is by improving the properties of the core. Also, increased case depth is attended by greater internal stresses after hardening and greater tendency to spalling of the case.

For resistance to such service the steel to be case hardened should be selected on the basis of physical properties attainable in the core after a heat treatment.

The required core strength may be insured by the use of steels of sufficient carbon or alloys or both to give hardening (strengthening) to the desired degree.⁴ Carbon alone will not cause the development of high core properties except with high quenching rates, as in thin sections or with drastic cooling. Thus when accurate contours are to be preserved and a slower (oil) quench must be used, the core hardening qualities of carbon must be supplemented by alloying elements; the amount of these two effects being determined by the sections and strength requirements.⁵ Since the percentage of alloying elements is reflected in the cost of the steel, and since the higher alloy steels in general are more difficult to process both in machining and in heat treating operations, there is a growing tendency toward the use of moderately alloyed steels with carbon percentages higher than previously employed. Until a few years ago, "carburizing steels" had 0.08-0.25 carbon, the lower ranges being preferred. Today, however, gears and other automotive parts, for example, are being made to withstand higher stresses by the use of moderately alloyed steels with carbon contents up to 0.40%, and often the case depths are being decreased, as permissible in accordance with Fig. 1.

Selection of Steel

Plain Carbon Steels—In this class are those steels containing only carbon (in addition to the usual percentages of such elements as silicon and manganese), or such slight amounts of alloying elements that the critical cooling velocity of the carburized case is normally only reached by quenching in aqueous media. Chromium up to 0.30%, or manganese up to 1.5%, are sometimes deliberately added to the plain carbon steels to accentuate the hardness or wear resistance of the surface, but these quantities may not be sufficient to permit full hardening in normal sections with oil or similar media. Carbon above 0.25% is infrequently used in standard practice due to brittleness of such steels in the fully quenched core. Core strengths of about 100,000 psi. with adequate toughness can rarely be exceeded with these steels. Heat treatment is simple and easily controlled.

Moderately Alloyed Steels—Those steels containing from 1-2% total alloying elements such as nickel, chromium, manganese, vanadium, and molybdenum, in addition to carbon, have sufficient hardenability that maximum hardness is usually attained by oil quenching, and desired core properties up to a tensile strength of 175,000-190,000 psi. are obtainable with suitable toughness by selection of analysis. In this class also fall the steels containing 0.20 to 0.30% molybdenum with no other alloys, made with controlled hardenability. Carbon content up to 0.40% may be specified to increase the core strength, the alloys providing the required toughness and depth-hardening characteristics. The differences between the various alloy types in this classification are difficult to demonstrate, being easily overshadowed by differences in processing technique and individual preferences.⁶ In general, there is a growing tendency toward the use of chromium as the principal alloying element due to decreased likelihood of austenite retention. The ready response of steels of this general class to heat treatment has permitted simple and accurate heat treating procedures to be established.

High Alloy Carburizing Steels—In some instances the sections and service requirements are such that a total of alloying elements over 2% must be used to give the desired core properties. The elements used are the same as above, but carbon content is held to 0.20 maximum because of the intense hardening power of these steels. Low quenching rate is required to harden to the maximum. Extreme core toughness and strength may be developed. The cost of steel and processing limits the use of these steels. Probability of austenite retention in the hardened case necessitates special, sometimes elaborate, heat treating cycles.

Grain Size and Abnormality—The grain growth tendency of a specific piece of steel at the carburizing temperature has a marked effect on physical properties and distortion after subsequent hardening. Steels of McQuaid-Ehn grain size of 5 or finer are almost invariably preferred and usually demanded. In a limited number of applications, the greater hardenability of the coarser grained steels warrants their

use in spite of increased distortion and reduced toughness.¹ Abnormality often accompanies fine grain in the McQuaid-Ehn test. Although the cooling velocity for full hardening must be greater for an abnormal than a normal steel of a given analysis, the change in critical rate is marked only in plain carbon steels when NaCl or NaOH solution is often required in quenching these to avoid soft spots. "Normal" steel is therefore frequently specified in the plain carbon types where freedom from soft spots after water quenching is required. Specifications as to normality are, however, rarely used in the alloy types. Abnormality, implying rapid spheroidization of carbides, may be definitely advantageous in avoiding residual networks of carbide after certain treatments.

Selection of Case Type and Depth

Case Depth—For ordinary engineering application several combinations of case depth and steel analysis may be used. In accordance with the Woodvine diagram, Fig. 1, an increase in core strength, accomplished by increasing alloy content or carbon content or both, permits a reduction in the depth of case required to resist bending stresses. Likewise, if compressive loading is to be resisted, an increase in core hardness will aid in giving a nondeflecting case, as will increased case depth. For resistance to abrasion only, service life will usually be proportional to case depth alone. Obviously, therefore, a wide range of case depths may be employed on any given part, consideration of over-all properties and manufacturing economy determining the steel analysis and selected depth.

As shown by time-penetration curves in the article on Mechanism of Carburizing, case depth increases rapidly with short times at heat, but after approximately 8 hr. the rate of penetration reaches a low and constant value. Consequently, case depth specifications are kept low enough that time required is not excessive. Carburizing costs include not only labor, which is little affected by increased time in furnace, but also furnace and heat resisting alloy costs.

The most common case depth is probably 0.045-0.060 in. Such a depth is obtained in 8 hr. at 1700°F.

Decrease in depth may be permitted when service is light or when core properties are improved by use of higher carbon or alloy content. As discussed later, this principle is being increasingly applied to gears, giving a product economical as regards steel and processing cost, as well as meeting the requirements indicated by the Woodvine diagram. Small or thin parts may of necessity be made with shallow case because of the brittleness which would otherwise result. A frequently applied rule-of-thumb states that the thickness of the case must not exceed one-sixth the section, if toughness is to be had.

Increased case beyond the normal depth is expensive to attain, and should only be specified when demanded by service requirements. Heavy duty gears, for example, are often made with case depth of 0.060-0.090 in. and parts requiring long life under highly abrasive conditions may have cases as much as $\frac{1}{4}$ in. deep. If much of the case is to be removed by grinding, obviously this must be allowed for in carburizing.

In connection with selection of case depth, it is well to bear in mind that, as shown in the article on Mechanism of Carburizing, the maximum carbon content and thus the maximum actual hardness at the surface are relatively independent of case depth. However, if the hardness test to be applied involves a heavy load with considerable penetration of the piece, a relatively deep case may be necessary to give a satisfactory hardness test result. For example, a high Rockwell C reading can be obtained only with cases having a hard layer over 0.025 in. deep, yet a case but 0.005 in. deep will give as great file hardness as the deeper cases. The readings obtained also depend on the support given the case by the core. Allowance should be made for these factors in selecting test methods for use with lighter cases.

Table I, from Boegehold and Tobin, summarizes typical applications and requirements.²

Type of Case—For two reasons it may be desirable to avoid a hypereutectoid layer. First, if the work is slowly cooled from carburizing, proeutectoid cementite will be rejected to the grain boundaries, usually forming a network. This will be redissolved in the hardening treatment but slowly, especially if the carbides are complex, and only if heated to the required A_{cm} temperature. Residual grain-boundary cementite in the finished piece is a frequent cause for failure due to brittleness. Second, even though direct quenching is employed and the separation of proeutectoid cementite inhibited, the hypereutectoid carbon content will tend

Table I
Typical Automotive Carburizing Applications and Requirements*

Case Depth	Typical Parts Made from Low Carbon Steel	Surface Condition When Treated	Requirements	Typical Parts Made from Medium Carbon Steel	Requirements
Up to 0.020"	Push Rod Balls Push Rod Sockets Speedometer Gears Shackle Bolts Shifter Forks The Rod Ball Studs The Rod Ball Stud Sockets Water Pump Shafts	Finished before treatment except for possible polishing operation. When nitrided 0.0003" to 0.001" per side removed for maximum wear resistance. Finished before treatment except for possible polishing operation. Generally semi-finished before treatment and finish ground after treatment.	High degree of wear resistance. Clean surface after treatment. High degree of wear resistance. Sufficient strength to withstand service loads. Enough case to permit finish grinding and maintain high hardness for necessary wear resistance.	Transmission Gears. Transmission Main Shafts and Synchronizer Sleeves. (Surface generally finished before treatment.)	Maintain or increase surface carbon for higher degree of wear resistance and greater fatigue resistance to high occasional or shock loading. Clean surface after treatment.
0.020" to 0.40"	Pitman Arm Ball Studs Intermediate Steering Arm Ball Studs Steering Arm Bushings Valve Rocker Arms Shafts Gear Shifter Shafts Brake and Clutch Pedal Shafts Water Pump Shafts	Finished before treatment except for lapping operation.	High wear resistance to resist sliding, rolling or friction of abrasive nature. Resistance to heavy crushing. Resistance to high alternate bending stresses.	Transmission Gears. Ring Gears. Drive Pinions. (Surface finished before treatment except for lapping operation)	Increase carbon content at surface for greater wear resistance, load carrying ability and fatigue resistance. Clean surface after treatment.
0.040" to 0.060"	Ring Gears Drive Pinions Transmission Gears Side Gears Side Pinions Piston Pins Steering Knuckle Pins Side Pinion Axes Reverse Idler Gear Shafts Counter Gear Shafts	Finished before treatment except for lapping operation. Semi-finished before treatment. Finish ground after treatment.	High wear resistance to resist sliding, rolling or friction of abrasive nature. Resistance to heavy crushing. Resistance to high alternate bending stresses. Operate frequently in bronze bushings. High wear resistance. Resistance to relatively high unit loads that cause Brinelling. Resistance to fairly high alternate bending stresses. King pins also require resistance to high instantaneous or shock loads.		
Over 0.060"	Roller Bearings **Camshafts	Semi-finished before treatment	Resistance to heavy rolling action. High wear resistance. Resistance to shock. Resistance to relatively high unit loads with a rapid sliding action.		

As service becomes more severe as in trucks and buses, the depth of case for corresponding parts may be somewhat deeper and the general tendency is to change to a steel which permits better physical properties, especially in the core.
 *More case than actually necessary to satisfy service requirements put on parts of such length as these in order to avoid necessity of straightening to extremely accurate degree before grinding.
 **Carburize deeper than necessary to satisfy service requirements to compensate for inaccuracies of machining due to length of these parts, distortion due to heat treatment and insure sufficient case after grinding for necessary hardness and wear resistance.

to increase austenite retention. For most applications a martensitic case free from austenite is preferable, consequently, if the steel is highly alloyed and thus susceptible to austenite retention, carbon content of the case should be held to the lowest amount compatible with full hardness, usually eutectoid content.

In certain applications, presence of cementite in the case is desirable to aid in wear resistance. For such applications it is important that the carbon content be high, the excess carbides being preferably in spheroidal form.

Heat Treatment Classification—A carburized piece must be regarded as a duplex material, that is, a high carbon surface, and a low carbon core, with a more or less gradual transition from one to the other. Two critical temperatures are thus involved in hardening, and the excess carbide of the case may or may not be dissolved at the hardening temperature selected.

Table II
Heat Treatment Classifications

**Spheroidization of excess carbide by subcritical treatment may be used to decrease austenite retention.

Fig. 2 illustrates the requirements and summarizes the usual methods by which carburized work is heat treated,⁸ and Table II shows critical temperatures and preferred treatments for usual carburizing steels.

Annealing—If subsequent distortion is to be minimized, the annealing temperature should be at least 50° above any temperature to be used later (carburizing). This will insure absence of pent-up stresses which might later cause distortion. Rate of cooling from the annealing temperature must be regulated to give uniformity from piece to piece, and to provide the required structure for best machinability. The carburizing operation and the later hardening are severe treatments, so maximum freedom from internal stresses must be provided by careful annealing practice on any but the simplest shaped parts.

Carburizing—Type of case and its depth must be carefully controlled.^{1,9} The temperature employed will usually be 1650-1700°F. to give a fair rate of penetration without unduly increasing furnace costs. Uniform temperatures must be provided to produce uniform carburizing, hardening response, and to control distortion.

Cooling from Carburizing—Since carburizing is conducted above the critical temperature of case and core, hardening of both will obviously occur if the work is cooled from this operation faster than the critical cooling rate.¹⁰ Prior to the advent of steels controlled to maintain a fine grain size at carburizing temperatures, such "direct quenching" was useful only for parts of regular shape and section because of the danger of cracking and distortion. Currently, however, an increasing portion of carburized work is being direct quenched into a suitable coolant, and in most cases if a fine grain steel is used, distortion is found to be lower and more regular than if parts are slowly cooled and then reheated for hardening. The greater difficulty of handling work from the higher temperature (carburizing) and in the quantities which are delivered discontinuously from carburizing furnaces, as opposed to reheating for hardening, have led some to prefer the latter procedure. A further handicap to the full use of direct quenching is the greater tendency toward reten-

tion of austenite in the hardened case, due to the higher temperature and increased cooling velocity." The higher alloy steels can rarely be used in the direct quenched condition for this reason, and many of the moderate alloy steels retain sufficient austenite so that the treatment is not acceptable, especially when parts will be subject to rolling under load (such as spiral or hypoid gears). Retention of austenite and distortion may be decreased in direct quenching by retarded cooling to a temperature above the A_r before quenching. This may be accomplished by transferring the work to a furnace held just above A_r , and stabilizing the work temperature at this level before quenching; a cyanide bath may be used, thus simultaneously accentuating surface hardness. Quenching from the carburizing temperature may be followed by reheating above the A_c of the case to give maximum refinement thereof, with minimum austenite retention. Direct quenching will give highest attainable strength and hardness of core, with toughness lower than maximum; the case will be file hard, penetration hardness being with higher alloy steels somewhat below maximum, due to retention of austenite; excess carbide will be dissolved, and the embrittling effect of a network of grain-boundary cementite will be absent.

Most work subsequently to be water quenched is either slowly cooled from the carburizing operation or oil quenched to give some refinement to the core without danger of cracking or severe distortion.

Separate Hardening Treatments—As indicated in Fig. 2, several types of hardening treatments may be applied when work is reheated after cooling from carburizing, depending on whether case, core, or both are to be hardened. Most nearly approaching direct quenching is the use of a single reheat to a temperature higher than the critical point of the core (and of course, the case). Maximum core strength may be attained, with fair toughness; excess carbide in the case may be dissolved, and austenite will be retained in the higher alloy steels, although not as much as by direct quenching; distortion will be higher than by the latter method, but may be held within acceptable limits. This treatment, like direct quenching, is rarely applied to plain carbon steels.

Reheating to a temperature only above the critical point of the case may be employed either after slow cooling or quenching from carburizing.

Under the first of these conditions, the core will be soft and moderately tough due to the absence of any refining treatment; the case will be hard, but due to undissolved excess carbide, may be brittle; distortion will be low due to absence of core quench, but adhesion between case and core may be inadequate leading to easy spalling of case. If, however, the work has been direct quenched, a high degree of refinement results from this combination of treatments. The core is fully refined, having high toughness with low hardness; the case will be fully hardened, with good toughness due to absence of cementite as network; distortion will be considerable. Slow cooling from carburizing, followed by a reheat and quench from above the core critical temperature, and then a quench from above the critical point of the case, will give similar results but with the maximum possible refinement, coupled with a high degree of distortion. This latter treatment is historically the most important, the once universal "double quench."³ Present control of steels for grain growth characteristics, coupled with the demand for higher strength cores, and a realization of the futility of high core toughness and impact values, has rendered this treatment of declining use and interest.

A single reheating treatment may be carried on at a temperature above the case critical point but below the core critical point; with such hardening, the core is partially refined and quenched, the case slightly improved due to some solution of excess cementite. This is rarely used due to poor resultant over-all physical properties.

The reheating for hardening is sometimes preceded by a treatment at a sub-critical temperature, for example, 1200-1300°F., for a sufficient time to give partial coalescence and spheroidization of the proeutectoid cementite, thus reducing the tendency toward austenite retention in the subsequent hardening treatment.

Tempering—Internal stresses from quenching will be somewhat relieved and resistance to cracking in grinding operations improved by reheating the hardened work to the highest temperature (usually 275 to 350°) which will not appreciably reduce the hardness and wear resistance of the case. The tempering treatment is frequently omitted. Some stress relief is offered by any washing operation conducted at or near the temperature of boiling water.

Typical Applications—Gears constitute one of the most important type of parts to which the carburizing process is applied. Because of the high design loads in

bending and compression, case hardened gears are usually chosen for heaviest service. The design loads, theoretically high, may be tremendously increased if tooth profile or contact is improper, so that distortion is a prime consideration in selection of material and treatment for carburized gears.

Steel to be used will be chosen in accordance with the principles previously discussed. The required core physical properties determine the grade or amount of alloy, and the manufacturing and heat treating preferences determine the specific steel and processing to be used. Quenching is usually in oil, because water, and the more drastic media may cause an unacceptable amount of distortion. The plain carbon, hardening water types of steel are, therefore, rarely used, where distortion is an important factor, the majority of requirements being met by steels of the moderately alloyed class such as S.A.E. 3100, 4100, 4600, 5100 and 6100 series. When the highest core physical properties are demanded, the higher alloy types may be used.

Fig. 1—Diagram indicating the fatigue range in carburizing steels (after Woodvine²).

From consideration of the stress diagram (Fig. 1) it is obvious that as higher stresses are imposed, resistance may be increased by increasing case depth (costly and, due to decreased tough core, embrittling) or by increasing core strength. Or, with constant stress conditions, increased core strength will permit reduced case depth. For this reason there is a growing use of higher carbon alloy steels for carburized gears, the case depth being reduced as is then permissible.

The shorter carburizing times make such procedures more economical. This combination of hard core and shallow case was also arrived at from consideration of the known advantages of cyaniding or otherwise shallow case hardening on the usual oil hardened gears of 0.35-0.50% carbon moderately alloyed steels. The shallow case required may be given by gas carburizing or cyaniding as a

simple extension of the normal heating cycle for hardening."

Since minimum and regular distortion is demanded in gears, steels with McQuaid-Ehn grain size of 5 or finer, usually 6 to 8, are customarily specified.

Annealing practice must be carefully controlled, a temperature of at least 50° above the subsequent carburizing temperature being used to insure full stress relief, and regulated cooling for best machinability is provided.

Hardening treatment should be selected in accordance with the previous discussion, the simplest treatments being preferable to give least distortion, but austenite retention must be held to a minimum, particularly when the gears are subject to high sliding loads such as in hypoid or worm gearing. Regulation of carbon content of case and of quenching temperature and velocity will assist in reducing austenite.

Camshafts—Selection of steel for such parts as these may be made in accordance with the principles previously discussed. Steels of the plain carbon and moderately alloyed types are used, surface hardness and wear resistance being a prime consideration. Since grinding after hardening is necessary, distortion must be kept low so that excessive straightening is not required. Careful annealing at a temperature well above carburizing temperature will aid in minimizing distortion. Hardening treatments employed are usually of the simple reheat type, shown as treatment "A" in Fig. 2, core properties being relatively less important than freedom from distortion. Quenching is frequently done in hardening machines wherein the piece is rotated while held in guides, thus holding straight enough that additional straightening is not required.

To facilitate straightening when necessary, areas of the shafts where the case is of no value may be protected during carburizing or the case removed therefrom by machining, so that after hardening these portions are ductile and permit bending as required.

Piston Pins—Steel for piston pins is selected on the same basis as for camshafts, the carbon and lower alloy types being most frequently used. In some cases, however, service loads may be sufficiently high that the use of higher alloyed steel may be demanded. Heat treatment should be selected as described above. Center

holes are often plugged to prevent carburizing inside with the consequent reduction of available thickness of tough core.

Spline Shafts—The principles already suggested apply to the selection of steel and treatment for spline shafts. The moderately alloyed types are preferred unless design loads demand greater stress resistance. Compressive load on the case due to pressure of the gear on the spline will govern the case depth required, while torsional and bending loads will determine core properties needed. Oil quenching is preferred for low distortion.

Fig. 2—Diagrammatic representation of various hardening treatments for carburized steels and summary of case and core properties⁸.

Treatment	Case	Core
A (Best adapted to fine grained steels.)	Refined; excess carbide not dissolved.	Unrefined; soft and machinable.
B (Best adapted to fine grained steels.)	Slightly coarsened; some solution of excess carbide.	Partially refined; stronger and tougher than (A).
C (Best adapted to fine grained steels.)	Somewhat coarsened; solution of excess carbide favored; austenite retention promoted in highly alloy steels	Refined; maximum core strength and hardness. Better combination of strength and ductility than (B).
D (Best treatment for coarse grained steels.)	Refined; solution of excess carbide favored; austenite retention minimized.	Refined; soft and machinable; maximum toughness and resistance to impact.
E (Adapted to fine grained steels only.)	Unrefined with excess carbide dissolved; austenite retained; distortion minimized; file proof when carbon is high.	Unrefined but hardened.
F (Adapted to fine grained steels only.)	Refined; solution of excess carbide favored; austenite retention minimized.	Unrefined; fair toughness.

Pack Carburizing

By H. W. McQuaid*

Chemical Reactions—With solid carburizers, nascent carbon is formed, on the surface of the steel, by the decomposition of carbon monoxide into carbon and carbon dioxide. The carbon dioxide formed reacts immediately with the incandescent carbon in the compound to form fresh carbon monoxide. This process is repeated as long as there is ample incandescent carbon present to react with the excess of carbon dioxide. The decomposition of carbon monoxide occurs at the surface of the steel which must be at such a temperature that the nascent carbon formed will go into solution in the steel itself.

Carburizing Compound—The usual commercial carburizing compound contains a mixture of approximately 20% alkaline or metallic carbonates bound to a hardwood charcoal by the use of oil, tar or molasses. This carbonate energizer is generally in the form of barium carbonate with occasionally a small percentage of sodium and calcium carbonate. There is usually added approximately 20% of coke as a diluent. The presence of the coke increases the rate of transfer of heat through the compound and hence is of value in obtaining uniform temperatures.

Because of the loss of the carbonate energizer, the powdering of the compound, and the burning in service, new compound is added before using again. It is necessary to have approximately 8% of the carbonate energizer present in the mixed compound. A percentage greater than this has little effect on the rate of carburization, whereas a decrease in energizer much below 8% retards the carburizing action and decreases the maximum surface carbon content. The addition of new compound will vary according to the care used in handling, the amount of direct quenching which is done, and the type of binder used in the compound. If care is used in the selection of boxes and the handling of the compound it is possible in most plants to use at least five parts of old with one part new compound, and some plants are operating with smaller additions of new than this. In many plants, however, the conditions are such that more new compound is required and it is not unusual to find plants making an addition of one part new compound to three parts used compound.

There are available carburizing compounds which do not consist essentially of charcoal with a carbonate energizer. Carburizing compounds have been made from various combinations of organic materials such as charred leather, burnt bone, raw bone, bone or bone with charcoal. These compounds will give satisfactory results when properly applied. They are relatively expensive and if no energizer is used their carburizing action is slow. Large quantities of bone black compound containing a relatively low percentage of energizer have been used for applications where low carbon cases are desirable. There have also been large quantities of carburizing compound used in which a water soluble energizer has been impregnated in a very dense charcoal. These compounds will usually give satisfactory results.

Recently compounds have appeared on the market which vary greatly from the standard in that they do not use charcoal but substitute a special type of coke. Other compounds have been developed which do not use a carbonate type of energizer.

Selection of Carburizing Compound—In selecting a carburizing compound there are many factors to consider. The handling equipment is an important factor as well as the quenching methods. With work cooled in a well designed box where the compound is not subject to exposure to air while at a red heat, it is not necessary to give much consideration to the burning characteristics. Where there is much quenching from the box, the rate of burning is an important economic factor and should be considered in selecting a compound.

Since the amount of new compound used is determined by the energizer retained by the used compound the method of incorporating the energizer is of importance. The cost of a compound should be based on lb. of satisfactory work per lb. of compound per hr.

The coated compound is at a disadvantage when compared to the impregnated compound except where handling and cooling conditions are exceptionally favorable.

*Metallurgist, Republic Steel Corp., Cleveland.

Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

If, however, no attempt is made to take advantage of a more stable compound by increasing the ratio of used compound to new, then the more expensive compound is of little advantage.

Packing—The packing of work in the compound is a dusty and somewhat disagreeable operation. For this reason the grouping of boxes, work, and compound should be carefully worked out to provide a minimum of compound handling. The work should come to the packer, if possible, already stacked and sorted, preferably on open trays or in pans.

A small layer of compound is first put in the empty box. This layer should be approximately one in. in depth although with lighter work this can be reduced to $\frac{1}{2}$ in. The minimum amount of compound should be used and this depends on the design of the box and the type of work. If the boxes are warped badly, more compound must be used on the top to prevent exposure of the work by burning away of the compound. Ordinarily, with alloy boxes, much less compound can be used than is common practice. The compound is a most excellent heat insulator while the metal is a very good conductor. Therefore, any increase in compound over the minimum necessary to support the work will result in an immediate and important increase in heating time. An increase of $\frac{1}{2}$ in. in compound between the work and the wall of the box is equivalent to increasing the wall thickness by many inches.

It is the usual practice to remove the dust and fine particles by screening, and between rough handling and the screening a large percentage of energizer and charcoal is wasted. The ordinary coated charcoal compound is extremely friable and must be handled with great care. If due attention is given to this problem the amount of compound used can be greatly reduced. Some of the conveyors, storage arrangements, and cleaning devices destroy so much carburizing compound that they become a liability rather than an asset.

Carburizing Boxes—While heat resisting alloy boxes have become quite standard, there are still many applications where rolled steel or cast steel boxes have an advantage. The heat resisting alloy boxes are usually made from a nickel chromium combination. The heat resisting alloy can be obtained either in the sheet form or as a casting. Both types have their advocates. The cast form is generally the least expensive especially where boxes are of a nonsymmetrical design. It is possible to obtain the cast boxes with a wall thickness which compares favorably to that of rolled sheets, and because of this there has been a general tendency toward a reduction in thickness of the walls of cast carburizing containers. The sheet alloy boxes are generally used for cylindrical shapes and have proven quite successful in these applications providing the welding is properly done. A large percentage of the failures with the sheet alloy boxes has been caused by poor welding.

Before a decision is made to use heat resisting alloys for carburizing boxes, a careful investigation should be made to determine the services expected from the containers. For boxes which are infrequently used and especially where the work being carburized is large and nonsymmetrical in section, cast steel or welded steel plate often prove more economical than the much higher priced alloy boxes. As a rule, however, where boxes are frequently used and the shape and size of the pieces do not require boxes of excessive size, the best heat resisting alloy will prove economical.

The design of the box* and the method of packing influence the carburizing results. Whenever possible work should be packed with its longest dimension vertical. This is an important requirement with shafts and stem pinions. Vertical packing permits vertical quenching with the least tendency of the tongs to distort the hot work.

Uniform heating is important and therefore the cylindrical box is to be preferred to rectangular boxes where the corners heat at a different rate than the sides, and where the work in the corners comes to heat before work in the center. Center tubes should be used wherever possible. These can be designed as integral with the box or where they must be removed to facilitate handling the work they can be separate.

Carburizing Temperatures and Case Depths—For steels of the fine grained type a carburizing temperature of 1675-1700°F. will be satisfactory. There are, however, many carburizing furnaces operating at 1725°F. or even 1750°F. with good results. These are usually continuous furnaces with carefully controlled cycles.

*R. W. Rousch and A. C. Dames, A Study of Commercial Carburizing Containers, Trans., A.S.M. v. 26, 1938, p. 646.

For some steels, especially the higher nickel alloy steels, lower carburizing temperatures are used. These steels use a temperature of 1625-1650°F. The same temperature is used in some plants to reduce warpage to a minimum. For work having a small section where the case depth must be controlled to a maximum of a few thousandths still lower carburizing temperatures are employed, and in some applications 1550°F. is used with a bone-base compound low in energizer.

Even with the best of furnaces and practice at 1700°F. it is difficult to obtain a total variation from maximum to minimum in a given furnace load of less than 0.010 in. in case depth. Pack carburizing is at a disadvantage in producing a case depth of less than 0.025 in., unless boxes are properly designed and work scientifically packed to eliminate temperature variation. With the standard practice of today case depths of less than 0.025 in. should not be specified for pack carburized work. For these light cases a carburizing temperature of 1625-1650°F. is suggested.

It is difficult to control the maximum carbon content in the case of a packed carburized part. Since the rate of evolution of carburizing gas in pack carburizing is fixed and is practically always in excess of the amount required to supply the necessary carbon for a saturated surface, it is customary in pack carburizing to obtain a saturated outside surface layer. If the energizer is deliberately controlled to reduce the carburizing effect, which can usually only be conveniently done in a bone compound, it is possible to obtain cases lower than the maximum which would be obtained under ordinary conditions at the carburizing temperature. The total carbon above the eutectoid will be greater as the carburizing temperature increases, but the maximum surface carbon will increase as the carburizing temperature decreases. This is because the solubility of the steel for carbon increases with increasing temperature. At low carburizing temperature the surface becomes supersaturated with carbon because of the inability of the carbon to diffuse.

Furnaces for Pack Carburizing—The fundamental requirement of pack carburizing is the elimination of variables which affect the temperature of the work. The first problem is to secure a furnace that can be controlled to plus or minus 10°F. and which heats uniformly throughout within 20°F.

As a rule, a furnace with the hearth at floor level is to be preferred, although there are exceptional cases where the hearth is more conveniently located at some distance above the floor. If the furnace is to be used for carburizing only and especially if the loaded boxes are of an appreciable size, the floor level furnace is much to be preferred. When quenching from the carburizing temperature, the floor level furnace has the advantage of minimum handling of the hot boxes.

Many of the so-called "standard" box type furnaces on the market, especially those built for oil fuel, are unsuitable for carburizing because of the great variation in temperature from one point to another. This type of furnace is especially apt to be low in temperature near the door and high in temperature at the back. When this difference is known it is often compensated for by putting work requiring a deep case in the back of the furnace and the lighter cased work in the front.

Where the volume of work will permit, a pusher type continuous furnace is desirable. The economical justification of this type furnace is closely related to box design and depth of case required. Where case depth is not too great and where boxes are designed to reduce the heating time to a minimum the continuous pusher type furnace has a great many applications. By careful attention to box design it will be found that the case depth can be held to reasonably close limits over a wide variation of work size. This requires careful attention to insure a reasonably close uniformity of work temperature at the time carburizing begins which usually means a temperature of approximately 1500°F. By using a minimum of carburizing compound the over-all carburizing time can be reduced to a minimum and a wide range of commercial work can be carburized to a 0.040-0.050 in. depth in nine hours or less in the furnace at 1700°F. A total of nine hours time in the furnace means that approximately five hours are used in bringing the work to 1700°F. since a case depth of 0.040-0.050 in. will be obtained in four hours at 1700°F.

A nine or ten hour cycle in a continuous pusher furnace 16 ft. long using two rows of 10 in. diameter containers should give approximately the same production as three of the usual type furnaces having a clear hearth area of 16 sq. ft.

The continuous furnace will produce more uniformly heated work, will lower fuel and container cost, and probably give less trouble due to variable case depth. The actual cost depends on the container design, the ability of the mechanical handling device of the continuous furnace to stand up, and the heating characteristics of the continuous furnace.

Gas Carburizing

By J. A. Dow*

Chemistry—In gas carburizing the carbon to be supplied to the steel is introduced to the work chamber, or retort, of the furnace in a gaseous state, rather than in a solid form which yields the desired gases on heating. For an understanding of the subject it is unnecessary to consider the reactions involved to be other than simple chemical reactions between gaseous compounds of carbon, and iron. Carbon is available in the gaseous state as carbon monoxide and as hydrocarbons, such as methane, ethane, propane, and butane, present in varying percentages in commercial fuel gases.

These hydrocarbons break down at carburizing temperatures almost completely to carbon and hydrogen if given sufficient time. This rate of breakdown, in terms of carbon liberated, is the maximum when the hydrocarbon is undiluted, and the minimum when the hydrocarbon is highly diluted by hydrogen or other gases. All the gaseous hydrocarbons will break down, if used undiluted for carburizing, at such rate as to liberate an excessive amount of carbon in the form of soot or coke on all exposed surfaces, in addition to the carbon combining with, or dissolving in the steel. If highly diluted, the rate of reaction with the steel is slow as compared to the possible rate of carbon diffusion into the steel, and the result is a low carbon and relatively shallow case in a given time. With increasing concentrations of hydrocarbon in a carburizing gas an upper limit in carburizing rate is reached, this limit being apparently the maximum rate at which carbon will diffuse into steel at the temperature used. Increases in hydrocarbon concentration beyond this point result in increasing free carbon deposit.

For uniform carburizing it is necessary to maintain in all parts of the furnace work chamber, either an uniform concentration of hydrocarbon gas or concentrations above that which produces the maximum rate of carburizing. High hydrocarbon concentrations, on the other hand, cause deposition of free carbon in a state and quantity which impedes further interaction of the gaseous carbon compounds and the steel, and cause shallow or spotty cases.

Certain gases, such as most natural gases, permit concentrations of hydrocarbon considerably above the minimum necessary for active carburizing without damaging carbon deposition. It is possible to feed these gases undiluted into the furnace retort, sufficient dilution being obtained by the mixing which immediately occurs with the partially spent, or stale, gas in the carburizing chamber. When using this method, sufficient feed of carburizing gas must be maintained to produce active carburizing at points in the retort farthest from the gas inlet. This minimum rate of gas feed may at the same time, however, cause high hydrocarbon concentration and excessive carbon deposition near the gas inlet. Where no provision is made for agitating the gas, or otherwise obtaining an uniform analysis throughout the chamber, there is a limit in the size of the furnace in which this method can be used.

Because of the gradual reduction in the hydrocarbon concentration of the gas as it passes through the retort when using this simple method, the case produced, when uniform throughout the charge, is usually a high carbon type undesirable for some parts. To overcome this, many plants have successfully adopted a method suggested by Day,¹ and Bramley and Lord² and described by Williams,⁴ and by Gable and Rowland.⁵ A period of diffusion following the carburizing, with no gas being introduced into the retort, permits the carbon to diffuse into the steel until the surface carbon content has dropped to the desired figure.

A variation in this method, having considerable merit, is to make the carburizing cycle a succession of carburizing and diffusion periods. This and a further modification by Guthrie and Wozasek³ are both described by Williams.⁴

For the heavier hydrocarbon gases, which break down under heat too rapidly to permit the use of the above method in its simplest form, and for controlling the carbon content of the case produced without the otherwise necessary diffusion period, and for better operation of continuous furnaces, many diluting gases have been developed with the object of controlling by dilution the rate at which carbon is liberated from the hydrocarbon source of carbon. These gases in many cases

*Engineer, Holcroft & Co., Detroit. Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, Chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

complicate the chemistry in the furnace, and can be divided into two general classes: those gases which contain decarburizing agents and those which do not.

The various gases which are introduced into carburizing retorts can be classified under headings as follows:

Carburizing Gases	Decarburizing Gases	Neutral Gases
Carbon monoxide, CO Methane, CH ₄ Ethane, C ₂ H ₆ Propane, C ₃ H ₈	Carbon dioxide, CO ₂ Water vapor, H ₂ O (oxygen burns to produce the above gases in the retort)	Hydrogen, H ₂ Nitrogen, N ₂

Carburizing Gases—1. Carbon Monoxide—Carbon monoxide carburizes by the mechanism of the two following reactions:

It will be noted that in giving up carbon to the iron an active decarburizing agent is in each case produced. Moreover the reactions are reversible. Both reactions proceed rapidly but liberate only a small amount of carbon before their equilibrium is reached and the reaction stops.

For this reason carbon monoxide can be considered an active carburizing agent, yet having only a small amount of carbon available per cubic foot of gas. Hence, carbon monoxide as a commercial carburizing gas is limited to the "skin" case hardening of medium carbon steels. It is, however, an excellent gas for diluting the heavier hydrocarbons, its action being for practical purposes in this case a neutral diluent. It does not introduce complications into the retort chemistry.

2. Methane—Methane is the slowest of the hydrocarbons in its rate of breakdown under heat, and for this reason is the most easily controlled. Where unaided by other hydrocarbon gases in small quantities, and when diluted by inert gases only, the methane concentration must be 40% or better to produce active carburizing at 1700°F. This concentration must be higher at lower temperatures and vice versa.

Methane can be considered a sluggish reacting gas carrying in the concentrations necessary for carburizing, a large amount of available carbon per unit of volume.

3. Ethane and Propane—Ethane and propane are alike in their behavior. Both break down rapidly at carburizing temperatures, and in concentrations above approximately 1% in neutral diluents, will deposit free soot on the work. These gases can be considered rapid-reacting gases carrying only a moderate amount of available carbon per unit of volume when mixed with neutral diluents in the proportions for best carburizing.

Ethane is present in almost all natural gases in varying percentages, while propane is available in a very pure state in liquid form.

Decarburizing Gases—Both carbon dioxide and water vapor are active decarburizing gases. They decarburize according to reactions (1) and (2) above, and when present in concentrations above 0.2% in the average carburizing gas mixture at 1700°F. tend to remove carbon from the steel. This decarburizing tendency can only be overcome by a concentration of hydrocarbon considerably in excess of that required for active carburizing when diluted by neutral gases only. For example, active carburizing is obtained from 1% of propane in neutral diluents, whereas, concentrations of this same gas up to 30% in the mixture fed to a furnace, have been found necessary to produce an equivalent result when the diluting medium contained approximately 2-3% of water vapor and carbon dioxide. When these gases are introduced to a carburizing chamber along with hydrocarbon gases, a rapid interaction of the two types of gas takes place, resulting in the disappearance of the decarburizing agents and the formation of carbon monoxide and hydrogen.

Neutral Gases—Atmospheric nitrogen does not apparently enter into any of the reactions of carburizing.

Hydrogen has been considered by many authors as an active decarburizing agent. To decarburize, hydrogen must combine with carbon according to the following reaction: $\text{C} + 2 \text{ H}_2 \rightarrow \text{CH}_4$

Since 2-3% of methane in a gaseous mixture prevents this reaction proceeding it is nonexistent in all gas carburizing.

Carburizing with Gaseous Mixtures Containing Decarburizing Gases—The diluting media of this type are the products of partial combustion of the hydrocarbon

gas and air, produced either in a separate gas generator, or in the furnace retort itself by the introduction of gas-air mixtures. If this combustion is carried out in a separate chamber it is the usual practice to condense out much of the water vapor formed, and to maintain as nearly as possible a constant analysis, with particular emphasis on the carbon dioxide and water vapor contents.

Two types of gas preparation units are in common use. They differ only in that the one type makes use of an externally heated retort or bank of tubes as a cracking chamber and can be operated with a richer gas-air mixture than the second type wherein the heat required for cracking the gas is supplied by the gas-air mixture itself, fired directly into a fire brick lined combustion chamber. A wider range of gas analyses may be obtained from the first type, whereas, it is difficult to produce a gas containing less than 4% carbon dioxide from the latter style. For carburizing, this prepared gas is mixed with natural gas or propane and fed to the carburizing chamber.

Another method in common use is to feed mixtures of propane and air, or natural gas and air directly to the carburizing chamber. In this instance, combustion immediately consumes the limited amount of air present, leaving a gaseous mixture containing the excess propane, or natural gas, and rather large percentages of the decarburizing gases, carbon dioxide, water vapor, and nitrogen.

The rate at which this type of gas mixture liberates carbon to all surfaces changes in its passage through the carburizing chamber, first increasing while the decarburizing agents are being removed by chemical interaction with the hydrocarbons, then later decreasing as the hydrocarbons are used up. It is possible with such a mixture to have slow carburizing near the gas inlet, a coke (carbon) deposit at the point of greatest activity, and slow carburizing in places remote from the inlet. Uniform carburizing throughout the work chamber may be obtained if sufficient hydrocarbon be used to overcome the effect of the decarburizing gases near the gas inlet, and a total volume of mixture adequate to supply the parts distant from the inlet. It is difficult with these mixtures to obtain uniform carburizing with other than high carbon cases unless provision be made for subsequent diffusion. Undesirable carbon deposition on the stock usually accompanies this method of carburizing.

Table I gives a list of gaseous mixtures of this type which have been used commercially. Multiple gas inlets with the rate of feed and composition different at the various inlets have given best results on larger furnaces, particularly of the continuous type. Carburizing with manufactured gas falls into this classification because of the presence of carbon dioxide and water vapor.

Table I
Gaseous Carburizing Mixtures Containing Decarburizing Gases

Carburizing Gas	Diluent Gas Analysis, % by Volume								% Carburizing Gas in Mixture*
	CO ₂	O ₂	H ₂ O	Illuminates	CO	H ₂	CH ₄	N ₂	
Natural Gas.....	4.5	0.0	2.5	8.0	9.0	0.5	Bal.	40
Natural Gas.....	0.4	0.3	2.5	0.3	15.8	30.1	15.0	Bal.	45
Propane				Air					33½
Propane	3.5	0.0	2.5	1.5	16.2	20.4	6.0	Bal.	20
City Gas	3.0	0.6	(dried)	4.3	12.1	44.6	29.8	5.6	

*These examples are taken from furnaces with multiple inlets and the figures in this column are based on the total gas fed to the furnace. The mixture, however, varied considerably from inlet to inlet.

Carburizing with Mixtures of Hydrocarbon and Neutral Gases—Dilution media of this type consist of the gases nitrogen, hydrogen, and carbon monoxide, with only minute quantities of carbon dioxide and water vapor present, and containing in some cases methane in percentages too low to have an appreciable carburizing effect.

When produced in a separate gas generator, a combusted gas-air mixture or straight air is passed through a heated bed of charcoal, wherein the carbon dioxide and water vapor react with the charcoal to produce carbon monoxide and hydrogen.

Another method in commercial practice is to use as the diluent medium the partially spent gas which issues from the gas outlet of the carburizing chamber. This partially spent gas is normally free of decarburizing agents and need be only slightly enriched by an addition of hydrocarbon and returned to the retort.

Carburizing with natural gas, or other pure hydrocarbon fed to the furnace in an undiluted state falls under this classification of carburizing since the spent gas

in the retort acts as a diluent to the incoming gas. Intermittent feeding of the gas addition at high velocity aids in producing thorough mixing and uniform hydrocarbon concentration throughout the chamber.

When using this type of diluting gas only two considerations enter into the control of the carburizing. (1) Sufficient dilution of the hydrocarbon gas fed to the retort must be used or obtained by agitation, to prevent excessive carbon deposition near the gas inlet and to maintain reasonably uniform gas analysis throughout the chamber. (2) The hydrocarbon addition is varied to produce the type of case desired.

High gas velocities have not resulted in nonuniform carburizing with this type of gas mixture.

Multiple inlets are an aid, reducing the amount of diluent gas necessary, where the carburizing agent is ethane or propane, but are not apparently necessary where methane is the principal carburizer except on large furnaces.

Light cases of from 0.005-0.015 in. in depth are being produced at temperatures of 1500-1550°F. in from 1-2 hr. total time in the furnace, with excellent control of case characteristics, by approximately 1% of propane or ethane in a dilution medium prepared from charcoal as described above. This type of gas carburizing is being used to replace cyaniding. Parts so treated come from the furnace entirely free from scale or soot.

Commercially Available Hydrocarbon Gases—Natural Gas—Natural gas consists chiefly of methane with ethane varying between 5-20%. For carburizing purposes it can be considered a hydrocarbon mixture, for practical purposes, free of decarburizing agents and containing but small percentages of neutral diluents. Sample analyses are given in Table II.

Table II
Analyses of Natural Gas^a
% by Volume

	CO ₂	O ₂	Illuminates	CO	H ₂	CH ₄	C ₂ H ₆	N ₂
Cleveland	0.2	0.2	0.8	..	80.7	18.0	0.5
Detroit	0.1	0.4	76.0	14.0	2.5
Pittsburgh	83.4	15.8	0.8
Canton, Ohio.....	..	1.2	0.8	1.0	..	79.2	16.1	1.7
Columbus, Ohio.....	..	0.2	..	0.8	..	80.7	17.0	1.5

Natural gas is to be preferred for gas carburizing because of its relative purity and because the high content of the rather sluggish reacting methane makes the gas easy to control.

Propane—Propane is obtainable in a pure state, bottled under pressure as a liquid which gasifies immediately under reduced pressure. (See article in this Handbook on Liquefied Petroleum Gases.) For carburizing purposes propane from the natural gas fields is to be preferred to that made at oil refineries. The latter type contains a rather high percentage of propylene which in certain gas mixtures deposits undesirable coke (carbon).

Because of its purity propane is a very satisfactory carburizing medium and is to be preferred to the gases listed below.

Butane—Butane is marketed in a manner similar to propane and is only being used for carburizing where it is also the fuel used for heating. It is quite sensitive to handle in carburizing and usually covers the work with heavy carbon deposits.

Manufactured Gas—Manufactured gas can have a wide range of analyses, depending on the method of its manufacture, and in most places a mixture of two types is supplied by the utility company, the proportions of each varying with the gas load.

For this reason and because of the rather high carbon dioxide and water vapor and low hydrocarbon content, manufactured gas is being used for carburizing in few places. To obtain active carburizing it is often necessary to either partially dry the gas or to enrich it with propane. Control is difficult because of the varying analysis. Manufactured gas is however quite satisfactory for making a diluent gas by some of the methods described, particularly the charcoal gas type, in which case propane as the enriching agent becomes a negligible item in operating costs even though purchased in bottles.

Composition of Manufactured Gas

% by Volume

	CO ₂	O ₂	Illuminates	CO	H ₂	CH ₄	C ₂ H ₆	N ₂
Coke Oven Gas	1.8	0.6	3.0	18.0	53.1	18.4	..	5.1
Carburetted Water Gas..	6.2	0.6	9.3	24.0	43.3	11.9	0.4	4.3

Furnace Types—Batch Type—Horizontal, rotating retort type furnace, gas or electrically heated, is used when suitable for parts which are not injured by the tumbling action which takes place during the operation. Because of the simplicity of the retort section and the absence of trays and fixtures this method of carburizing is the most economical. The tumbling action continuously removes soot from the parts, making the operation less sensitive to high hydrocarbon concentrations. Fixtures can in some instances be used for work which would be battered by the tumbling.

The vertical retort type, gas or electrically heated furnace, with and without means of mechanical agitation of the gas in the retort, produces uniform carburizing by regulation of gas mixtures, flow, and by the location of gas inlets. Mechanical agitation of the gas in the retort is sometimes used in this type of furnace. If satisfactorily applied, it eliminates rate of gas input as a factor in producing identical cases throughout the charge. This type is being built for operation with certain liquid hydrocarbons as the source of carbon.

In the horizontal stationary retort type, gas fired furnace, the work is carried on trays and fixtures and because of the size of the furnace a diluting gas is normally used. The retort life is greatly affected by the thermal shock due to the heavy charges of cold stock.

Continuous Type—Continuous gas carburizing furnaces are all of the pusher tray type. The work is carried on fixtures or trays, and may be built for automatic quenching, for hand quenching, or for slow cooling in a cooling zone built onto the discharge end of the carburizing zone.

Operating costs on these furnaces are usually considerably lower than with continuous pack carburizing furnaces when operated at close to capacity. The hourly operating cost however is almost as great when running at half capacity as at capacity. Design, and soundness and cleanness of the alloy in the muffle, trays and fixtures are important factors in costs.

Notes on the Operation of Gas Carburizing Furnaces—Case variation can be divided into three classes: (1) The variation which occurs on parts at different locations in a batch furnace, or in a cross section of the muffle in a continuous furnace. (2) The variation which occurs from heat to heat or day to day. (3) The variation in case on protruding and recessed surfaces of a single piece, or on the exposed and unexposed surfaces of parts stacked closely together.

1. The first type of nonuniform carburizing can be caused by temperature variation, which is a common occurrence in batch furnaces because of the difficulty of designing for door and end heat losses. The only other cause of this type of case variation is a gas of varying analysis throughout the work chamber.

If no diluting medium is being used, an increase in gas flow, additional gas inlets, or agitation of the gas in the furnace by intermittent feed or some form of mechanical circulation either inside the furnace or by a return pipe and gas booster outside the furnace will overcome this type of case variation.

If a diluting medium containing decarburizing agents is being used, the remedy depends on the location in the furnace with respect to the gas inlets of the zone of light cases, and has been previously discussed. This type of case variation due to varying gas analysis in the chamber rarely occurs when a diluting medium free from decarburizing gases is used providing there be adequate total flow.

Retort leaks can be the cause of a varying gas analysis in a carburizing chamber with all gas carburizing methods.

2. The case variation which occurs from day to day or heat to heat, may be caused by: (a) Change in the analysis of the carburizing or diluent gas. (b) Change in the condition of the muffle or other furnace alloy. The hydrocarbon gas fed to a furnace may have to be increased 50% or more above normal to overcome an oxidized muffle condition. Forty-eight hours may be required to completely condition an oxidized or new muffle. (c) The control thermocouple losing its accuracy.

3. The third type of case variation, heavy cases on protruding surfaces and light cases in recesses, is apparently more a function of the hydrocarbon concentration in the carburizing chamber than any other factor and may best be overcome by increasing the rate of feed of hydrocarbon. Where this variation occurs on the adjacent sides of adjacent parts it may be advisable to separate the parts somewhat more inasmuch as an increase in hydrocarbon feed usually causes somewhat dirtier stock.

An intermittent or on and off gas feed may be of help in remedying this condition.

No form of gas circulation can produce equal scavenging of spent gas from protruding and recessed surfaces, nor is apparently much of a factor in this type of case variation.

With equal tendencies to deposit soot and with other conditions constant, the higher the content of sluggish reacting methane in the carburizing gas in the retort, the better will be the uniformity of carburizing on exposed and recessed areas. Oil vapor, if it gets into the gas in the retort, works opposite to methane and causes bad case variations.

The formation of tar in a gas carburizing furnace which is indicated by coke (carbon) deposit on the work can best be corrected by the reduction in the rate of hydrocarbon feed. In batch operation it is advisable after an initial flushing of the retort to shut the gas off until the charge is fully at heat. Additions of water vapor, carbon dioxide, or air to the hydrocarbon gas seem to cause a greater reduction in the carburizing power of the gas than in the tendency toward tar formation. Oil in the pores of the alloy trays used in a continuous furnace has contributed to tar formation. Butane, and refinery propane containing propylene, are more difficult to handle in this respect than natural gas or the purer form of propane obtained from natural gas. A gradual increase in the hydrocarbon concentration of the gas in a furnace retort occurs in many instances for several hours after the gas is first turned on and can result in tar formation some hours after the start of the operation. A reduction in gas feed corrects this condition. Sulphur, if excessive in the muffle gas, can act as a powerful deterrent to carburizing.

A decarburized surface of a few ten-thousandths of an inch in thickness, and detectable with a file, can be produced almost instantly if work is allowed to stand in a decarburizing atmosphere just before quenching. The life of furnace muffles, trays and fixtures, is more a function of the cleanness of the metal and the soundness of the casting, and design, than of the nickel and chromium content of the metal.

Welds have not proven satisfactory where subjected to the action of carburizing gases.

Liquid Carburizing

By E. F. Davis*

Introduction—For many years chemical salts such as cyanides (prussiates) have been employed to impart a hardenable surface on wrought iron and low carbon steel. These were first used as powders and used in a blacksmith forge, but later immersion methods were installed whereby the parts were dipped into a molten bath and allowed to acquire a superficial case which would subsequently become file hard by quenching in water or oil.

Cyanide of sodium or potassium were usually preferred and have proved fairly satisfactory for case depths up to 0.010 in., but evidently the nitrides formed on the surface at low temperatures become an obstructing agent preventing rapid diffusion of the carbon so that the penetration rate is much reduced after an initial case of 0.004-0.0065 in. is formed. Although it is possible to carburize to any depth in cyanide alone, if the process is sufficiently prolonged, such a slow method is commercially impractical.

Development of Activated Baths—The early experiments employing the addition of an activating agent to a neutral or noncarburizing bath were for the purpose of utilizing the infusible calcium cyanamid. This was first exemplified by the German Deininger process, and later in this country by the Shimer process. These methods consisted of adding calcium cyanamid at intervals to a molten bath composed of a mixture of calcium and sodium chloride. In the Shimer process it was deemed necessary to submerge the cyanamid below the surface by means of a small metal basket containing the lumps of cyanamid. The bath was "re-activated" from time to time by replacing with fresh cyanamid. Later this process of submerging was eliminated by improvements in the method.

Types of Activated Baths—Both in Europe and the United States a number of activated bath formulae have been developed during recent years, utilizing, in addition to calcium cyanamid, polymerized hydrocyanic acid, or sodium or potassium cyanide with controlling chemicals. Controlling chemicals refer to certain salts such as fluorides or special catalysts which govern the decomposition of the cyanides. The latter type of bath has all the various constituents fused together and cast into lumps or coarsely powdered, and requires no additions at intervals of a separate activating material.

Carburizing with Activated Baths—The case depth limits that are most economical are generally placed between 0.010 and 0.030 in. Above 0.030 in. it is usually more cheaply done by standard pack or gas carburizing processes; hence its greatest field of utility is the gap between cyaniding and furnace carburizing where a closely controlled case is necessary, such as parts of thin section where the allowable variable is quite small. Variations as close as 0.003 in. can be obtained consistently.

When deep cases are obtained in activated baths the consumption of fuel is increased abnormally and pot life per ton of steel carburized is much reduced. If the temperature is increased to shorten the time, pot life is correspondingly lowered.

Temperature of Carburizing in Activated Baths—Most baths are operated between 1500 and 1650°F. The lower temperatures are usually employed when only a superficial case is desired similar to the cyaniding. Investigations by B. B. Beckwith† have shown little variation in ultimate results obtained from six different commercial activated compounds when the parts were treated under the same conditions of time and temperature. The reason for this is no doubt due to the fact that steel possesses definite rates of absorption and diffusion of carbides in accordance with the temperature attained, and is not influenced to any great extent by the richness of the carburizing agent at the surface.

Character of Case from Activated Baths—The character of the case in activated baths is different from that of cyanide. As a rule the case is richer in carbides and

Prepared for the Subcommittee on Carburizing. The membership of the subcommittee was as follows: R. B. Schenck, chairman; E. F. Davis, J. A. Dow, R. W. Schlumpf, H. W. McQuaid, and G. T. Williams.

†B. B. Beckwith, Liquid Bath Carburizing, Trans., A.S.M., 1938, v. 26, p. 752.

contains from 50-75% less nitrides. Nitrides are however present to some extent in the case obtained from nearly all the baths now in operation. However, nitrogen needles are seldom found in the carburized area of parts treated in activated baths, hence may lead to the belief that nitrides are absent. However, analysis of the layers of the case will show that some nitrides are present. These may vary from 0.05-0.30% in the outer zones. Another difference between the cyanide and activated case is that it is possible to obtain eutectoid and hypereutectoid case from these mediums and in composition resembles more the carburized than the cyanided case.

Advantages of Activated Carburizing—The case obtained from activated baths is less brittle than the cyanided due to less nitrides. Where a brittle case is objectionable, activated carburizing is often preferred. The activated case also tempers or softens more easily than the cyanided.

The presence of small amounts of nitrides in the activated case is really an advantage because it enables parts of thin section such as stampings, washers, small gears and other parts of small area to be file hard by an oil quench. A large percentage of these parts are made of S.A.E. 1010, 1020, 1120 and similar carbon steels, which otherwise might require a water quench to produce the necessary hardness. Oil quenching reduces the tendency toward brittleness and distortion.

Fig. 1—Case Depths for Activated Baths and Cyanide Baths. (Beckwith)

Furnaces for Activated Baths—Pot furnaces are used with cast steel, heat resisting alloy, or welded plate. The furnaces are either gas, oil, or electric fired. Where internal electrode heating is used on the activated baths no deterioration of the salt has been reported.

Requirements of an Ideal Activated Bath—1. No infusible residue should accumulate to contaminate the bath. 2. It should not require constant attention to keep it in operating condition. 3. It should not be sensitive to contamination with other salts used in heat treating operations. 4. It should be fluid and drain off readily when the parts are lifted out of the bath to keep take-out losses to a minimum. 5. It should be economical in price based upon volume weight molten. 6. It should wash from the parts readily. 7. It should carburize uniformly at all times. 8. It should not foam badly or corrode containers. 9. It should not be a health hazard to workers. 10. It should not produce excessive fumes at operating temperatures. 11. It should not promote rusting of parts. 12. The decomposition rate requiring additions of fresh salt should approximate the amount of loss by drag-out so the volume will not increase by deterioration sufficient to require frequent bailing-out and loss of material.

The carburizing rate based on three different activated baths operating at 1650°F. gave the following results:

Temperature, °F.	Time	Case Depth, In.
1650	45 min. to 1 hr.	0.010-0.015
1650	1 hr. to 1½ hr.	0.015-0.018
1650	1½ hr. to 2 hr.	0.018-0.022
1650	2 hr. to 2½ hr.	0.022-0.025
1650	2½ hr. to 3 hr.	0.025-0.027
1650	3 hr. to 3½ hr.	0.027-0.030

The size of the part, the type of furnace used, as well as the weight per furnace load would somewhat affect these figures. Some time is consumed to bring the parts to temperature and heavy charges of work would lower the bath temperature.

Case depth determinations by B. B. Beckwith† at different temperatures are given in Table I and Fig. 1.

Cyaniding

By H. B. Northrup*

Caution—Cyanides are violent poisons if allowed to come in contact with scratches or wounds, as for example, on the hands. They are fatally poisonous if taken internally. Fatally poisonous fumes are evolved when cyanides are brought into contact with acids.

Introduction—A hard superficial wearing surface or case can be rapidly and satisfactorily obtained on low carbon steels by subjecting those steels to the cyaniding or case hardening process. When steels are treated by this method they absorb both carbon and nitrogen from the molten salts, so that when they are quenched in water or a suitable oil they develop appreciable hardness in the case.

Due to its greater efficiency and to its lower cost, the use of sodium cyanide in place of the more expensive potassium cyanide is now practically universal. Sodium cyanide for case hardening is used in either of two ways: (1) As a powdered mixture into which the red hot steel is dipped or which is applied to the heated surface of the steel; and (2) as a molten bath into which the steel to be treated is immersed for a sufficient length of time for the reactions to take place.

Properties of Sodium Cyanide—Sodium cyanide is used in the case hardening of steel in four different strengths or grades. Each of these grades, because of its chemical composition, has individual properties as shown in Table I.

Molten sodium cyanide is quite rapidly decomposed when heated above 1580°F. in an open pot. The heavy white fumes which arise from the bath are not especially dangerous, although they are decidedly obnoxious for they irritate the mucous membrane in the nasal passages and thereby induce violent sneezing. This fume when disseminated in the air becomes almost entirely sodium carbonate which, while not dangerous or particularly detrimental to health or property, may become annoying. The escape of fume can be prevented by the installation of a fume-gathering and washing equipment. The suction fan equipment draws the fumes from the pots and passes them through a large washing drum and water spray (mist) before being vented into the outside air. The washers and the spray dissolve the sodium carbonate fume and precipitate any solids carried by the ventilating apparatus.

The chemistry of the decomposition of the bath involves the oxidation of the sodium cyanide to sodium cyanate by the application of heat and exposure to the air (oxygen) as follows:

Continued heating of this sodium cyanate in air (oxygen) forms sodium carbonate, carbon dioxide, and nitrogen as follows:

Table I
Properties of Sodium Cyanide

Grade	Sodium Cyanide, NaCN	Per Cent Sodium Carbonate, Na ₂ CO ₃	Sodium Chloride, NaCl	Melting Point °F.	Sp.gr. at 77°F.	Sp. gr. at 1580°F.	Appearance
96-98 ¹	97	2.3	trace	1040	1.50	1.10	white crystalline solid
75	75.3	3.5	22.2	1094	1.60	1.25	white fused solid
45	45.3	37.0	17.7	1058	1.80	1.40	white fused solid
30	30.0	40.0	30.0	1157	2.09	1.54	white fused solid

¹This grade contains 0.50% sodium cyanate (NaCNO) and 0.20% sodium hydroxide (NaOH). The sodium sulphide (Na₂S) is nil.

Sodium cyanide is a strong reducing agent in the molten state, readily reducing the oxides of most metals. It is deliquescent and gradually decomposes if left in an open container, due to the action of moisture and carbon dioxide. It is soluble in water and the solubility of the anhydrous salt is almost independent of the temperature.

*Director, Mineral Industries Extension, The Pa. State College, State College, Pa.

Steel will heat about four times faster in a molten lead bath than it will in a molten cyanide bath at the same temperature. This is due to the greater heat conductivity of the lead; lead is, therefore, a better production medium than cyanide. However, since slow and uniform heating of steel is advocated to produce most desirable results in any heat treatment, the cyanide method meets with favor because it produces a much milder heat transfer and does away also with special fixtures, necessary in lead hardening for submerging the steel under the surface of the bath.

Uses of Sodium Cyanide

Uses of 96-98% Sodium Cyanide—In the heat treatment of steel, powdered sodium cyanide (96-98% NaCN) is sprinkled upon red hot steel for case hardening; as a "sweetener" to replenish the cyanide content of depleted case carburizing baths; as a bath material for cyanide carburizing direct; and in admixture with potassium cyanide for nitriding steel by the bath immersion method.

Uses of 75% Sodium Cyanide—This mixture is sometimes used as a bath for cyanide carburizing direct, but because of the volatility of the cyanogen (CN) radical, its use in heavy production work is not recommended. It is more frequently used as a replenishing material to raise the cyanide content of depleted baths or to keep them at predetermined cyanide concentrations through regular additions.

Uses of 45% Sodium Cyanide—This mixture is recommended as a suitable bath for the general case carburizing of low carbon and alloy steels. It is very fluid at the operating temperature. The addition of "inerts" (sodium chloride and sodium carbonate) to sodium cyanide tends to retard the decomposition of the sodium cyanide without being detrimental to its case carburizing properties. When this mixture is used continuously in production work, its cyanide strength will of necessity need to be maintained nearly constant through the addition of either the 96-98% or the 75% sodium cyanide.

Uses of 30% Sodium Cyanide—Where the case carburization of low carbon and alloy steels is to be maintained under heavy production conditions, this strength mixture is preferable to any of the preceding. It has the lowest first cost and due to the addition of its inerts, the decomposition of the sodium cyanide of the bath is greatly retarded without being in any manner detrimental to its case carburizing properties.

It is necessary to maintain the strength of the bath constant through the addition of either the 96-98% or the 75% sodium cyanide. It is preferable to use the 96-98% sodium cyanide, because of the absence of inerts in that strength material. The bath is already loaded with sufficient inerts to "fix" the additions of the concentrated material, which should be added in stated amounts at regular intervals. If the cyanogen content of the bath is too low, the bath tends to decarburize and scale the work. "Drag-out" of the bath material is replenished as needed with the 30% sodium cyanide.

The Cyanide Bath—Baths of sodium cyanide are employed in connection with the heat treatment of steel to accomplish two definite purposes as follows: (1) To act as a heating or a reheating medium in connection with the hardening of steels or to prevent surface decarburization and to produce work with a clean surface; and (2) to act as a liquid case carburizing medium affording a quick, efficient, and economical means of obtaining a hard superficial wearing surface.

To accomplish the first purpose, the bath may be either the 30% sodium cyanide, or where a slight case is undesirable that strength material may be diluted with about an equal weight of sodium carbonate. An illustration of the use of the 30% sodium cyanide is the cyanide dip method frequently employed in the heat treatment of automobile transmission and ring gears. An illustration of the use of the diluted material is the heat treatment of tool and stainless steels. To accomplish the second purpose, a bath regulated to maintain a uniform 30% sodium cyanide concentration has been found to meet all the requirements.

Low carbon and alloy steels which are to be cyanided to produce a good wearing surface usually require the surface to be backed up by a fine grained, tough core. This requires the operating temperature of the bath to be in the neighborhood of 1600°F. Case depths and carbon concentrations for three steels are given in Table II. These results show the inefficiency of cyanide as a medium for obtaining deep carbon penetrations. They also show that with even a 1 hr. immersion the carbon concentration is insufficient to account for the extreme hardness obtained

from quenching cyanided steels. Usually immersions run from 30 min. to 1 hr. and produce case depths and carbon concentrations corresponding to those given in the table. Lowering the temperature will correspondingly and proportionately lower the results given in the table.

Since the results obtained in the practice of cyaniding steel are directly proportional to the four variables, time, temperature, mass, and cyanide concentration of the bath, the following data in Tables III, IV and V, all derived from the heat treatment of S.A.E. 1020 steel, show clearly the results of accepted practice involving these variables.

Within the time range of commercial cyaniding practice, practically no difference in case depth is evidenced by steels of different analysis. The nickel and

nickel-chromium steels, however, tend to give a nicer carbon gradient from case to core than do the carbon steels, but exhibit at the same time, a lower carbon concentration in the case.

The file hardness obtained after water quenching cyanided steel is due to more than the hardening properties imparted to the steel by the added carbon. Since one of the decomposition products of a sodium cyanide bath is nascent nitrogen, it follows that some of this nitrogen has combined with the iron of the steel with the formation of the extremely hard and brittle iron nitride.

Cases obtained by the cyanide process are both hard and wear resisting, although they are not of the high carbon concentration possible with solid commercial carburizing compounds.

Generally, the steels which are case carburized by packing in solid carburizing material or subjected to a carburizing gas can likewise be carburized by cyaniding. They are generally treated by the liquid bath method because of some particular advantage of the process, such as speed of production, the economies of the process, or the peculiar quality of hardness desired in the resultant case.

The cyaniding should in the majority of instances be carried out at a temperature just above the upper critical point of the core, and the steel should be quenched directly from the cyaniding heat. At this temperature the case, which does not approach a tool steel analysis and which has not been held for a sufficient length of time to cause brittleness through excessive grain growth, will quench to the desired hardness and the core will be thoroughly refined and tough.

Quenching of Cyanided Steels—Whether to quench in oil or water depends upon the service requirements the cyanided steels are to meet and the chemical composition of the steel. When water is used it should be as free as possible from dissolved gases, which have a tendency to produce soft spots, so for straight hardness quenching the water should not be air agitated. For maximum hardness and to alleviate warpage, the water should be moving, except where long or thin cyanided parts are to be quenched. It should be normally as cold as possible; variation of quenching water temperature between summer and winter has been known to produce hardness irregularities. Advantage may be taken of the greater hardening capacity of sodium hydroxide solutions or other special aqueous solutions.

For oil quenching a mineral oil should be used. The blended mineral-animal hydrocarbon oils should never be used for the quenching of cyanided steel, because the fatty matter of the animal oil will saponify with the decomposition product of the cyanide bath (alkali) causing the formation of a hard soap. This soap will not only retard the quenching speed of the oil, but may also clog the drains.

Hardness of Cyanided Steels—The usual requirement for the hardness of cyanided steel for shop production is "file hard". While this hardness value is subject to many ramifications, it is still the criterion for shop hardness testing. The Rockwell "C" impression and the scleroscope are also used for testing cyanide hardened surfaces.

The depth of the cyanided zone is best determined by means of the microscope. The cyanided case is composed of two fields which are distinct in character, a martensitic outer zone and a troostite-sorbite inner zone of lower carbon content. The case depth is usually determined by measuring the distance from the outer edge of the specimen to the center of the second zone.

Steels which are cyanided and which do not contain more than 0.65% carbon in the case cannot attribute their hardening power alone to their carbon content. Since one of the decomposition products of the cyanide bath is nitrogen, iron nitride is formed which is an extremely hard and brittle product. At the lower cyaniding temperatures (about 1425°F.) a considerable amount of iron nitride is observed in the form of nitride needles and patches. When the temperatures are in the neighborhood of 1550°F. few of the nitrides are observed, but it is generally accepted that this iron nitride in undistinguishable form produces the hardness otherwise unattainable from the carbon additions.

While the nitrogen absorption affects the hardness of the case, through the formation of iron nitrides, the core is not affected. Steel of the proper grade which has been cyanided above the critical range of the core and quenched into water will snap readily when subjected to stress. When the case is removed by grinding, it is found that the core possesses ductility. Therefore, the brittleness of the core is only apparent. The mechanism for the apparent brittleness may be

due largely to a notch effect in the core after a crack has been formed in the hard case.

Pot Life—The life of cyanide pots in fuel fired furnaces is, in general, an inverse function of the temperature of the combustion chamber. The higher the combustion chamber temperature, the lower will be the pot life. It has been reported¹ that where furnaces were changed from hand-operated to automatic control, the average life of cast steel pots was increased as much as 70%.

Cyanide Containers

Cast Iron Containers—Cast iron fails prematurely and rapidly due to growth. The free graphite of the cast iron grows when subjected to cyaniding temperatures for a considerable length of time, and causes distortion or cracking.

Pressed Steel Containers—Pressed steel containers are probably the most universally used and under proper furnace conditions give high economy. They are highly resistant to the action of molten cyanide, they are homogeneous throughout; and their cost is moderate and commensurate with the increased life of the container.

Cast Steel Containers—Cast steel containers also have a wide application and when of the proper composition and properly cast so as to be free from casting defects give satisfactory service.

Cast Alloy Containers—Nickel-chromium alloy containers have been developed which will give several hundred furnace hours. As a rule, the failure of the cast alloy containers is due to faulty foundry practice. When they are properly cast their higher cost is offset by their increased performance.

Cyanide Containers and Furnaces—The life of any container is shortened by the improper application of heat. As a rule, even physically sound containers will fall from this cause before they will fail from the corroding action of the molten cyanides which they contain. Fuel fired furnaces should, without exception, have their heat application at the top of the pot with the furnace vented at the bottom. In addition to this, with oil fired furnaces, the combustion chamber should be located adjacent to but outside the heating chamber. Such a change from the underfired principle has been known to increase the life of pressed steel pots over 200%. Insofar as pot life is concerned, electric heat applied to the outside of the pot excels all other methods of heat application.

It may be safely stated that the life of any container is in direct proportion to the effectiveness with which the pot is sealed to prevent cyanide from entering the heating chamber. Some furnaces and pots are so designed that it is practically impossible for the molten cyanide to creep into the combustion chamber. In furnaces which do not have specially designed seals, a most satisfactory seal against molten cyanide is obtained by placing a ring of dry powdered fire clay under the pot flange just before dropping the pot in place upon the furnace top.

Quite recently an electric furnace adaptable to cyanide hardening has been introduced and has proved very successful. The furnace operates on alternating current and consists of a well insulated cyanide container into which electrodes are placed which are immersed in the bath. The patented arrangement of the electrodes in the bath utilizes the electromagnetic forces in such a manner as to induce an automatic stirring action throughout the entire pot, tending to produce maximum uniformity of temperature distribution throughout the bath. The heat is generated directly by the resistance of the cyanide bath to the passage of the current. Claims for this improved equipment for the cyanide hardening room include: improved economy of operation; increased production; uniformity of bath temperature; improved uniformity of product; and improved working conditions.

Selective Carburization of Steels*

Introduction—Selective carburization is carried out for certain special purposes where it is desired to retain soft surface portions after hardening to permit machining, polishing, straightening, or to increase toughness of the piece.

Selective carburization may be accomplished in many ways, but only the principal methods will be considered here. In practice, it is more difficult to secure selective carburizing with gas carburizing than in compound.

1. **Excess Stock at the Surface Portion Desired Soft**—When machining the work, excess stock is left at portions desired soft. After the carburizing operation the piece is pot cooled. The excess stock is then machined off to below the case. The piece will then have a soft surface area following the hardening treatment. This is not properly selective carburizing, but for certain types of tool work, or where but few pieces are to be treated it is an excellent method of accomplishing results. Where threads or sharp corners are to be left soft, this method is, perhaps, the most reliable.

2. **Sand Packing**—The work is packed in sand, exposing only the desired portions to the carburizing compound. The line between the hard and soft portions will not be sharp, as the gas from the compound penetrates the sand to a slight depth. It cannot be used with compounds which have a high shrinkage, as the sand will be displaced, causing hard and soft spots at the protected points. The sand used should be fairly fine and reasonably free from dirt. It must also be thoroughly dried before packing or caking will occur, exposing surfaces which are to be protected. It is an advantage to have the sand at the bottom of the carburizing container and to subject the container to as little jarring as possible after the pieces have been placed in it.

3. **Covering Parts Desired Soft with Cement**—A satisfactory method for preventing carburization of tapped holes and bores of gears is to plug these parts with a cement composed of finely sifted fire clay mixed with sodium silicate (water glass). The proportions used (approximately 2 parts fire clay; 1 part sodium silicate; and about 1/10 part of water) should be regulated so as to secure a cement which will not crack or shrink excessively upon heating and firing. The addition of sand to the cement will sometimes assist in preventing shrinkage. After carburization the cement may be knocked out of the holes. Although this cement will form glass, it is possible by using care to apply this cement to external surfaces, but for this purpose it is not so satisfactory as other methods for selective carburizing. There are prepared cements on the market for this purpose.

Such parts as bushings, sleeves, and piston pins are often strung on close fitting steel rods which minimizes the case in the bore.

4. **Covering Parts Desired Hard with a Carbonaceous Cement**—Selective carburization is obtained by covering the portions of the article to be carburized with a carbonaceous paste or cement which acts as the carburizing compound. After subjecting the work to the proper temperature, the portions covered with the paste are carburized and the other portions of the article are unaffected. With this method the case will not be sharp, but will gradually slope to the portion of the work desired soft.

5. **Protection with Copper Forms**—Pure copper in the form of tubing, bars, cups, sleeves, and discs, is used to prevent carburization for tapped holes, piston pins and ends of shafts. The copper form is placed on, or in the work, as the case may be, with a clearance of not over $\frac{1}{64}$ in. This method is not completely efficient but markedly decreases both case depth and the carbon content of the case.

6. **Plating by Dipping in Copper Sulphate Solution**—A copper plate may be obtained which will partially prevent carbon penetration by either dipping in a copper sulphate solution, or applying the solution with a brush. The part desired soft is first thoroughly cleaned and then dipped in the solution. The part should

*This article was prepared by a committee appointed by the Hartford Chapter of the A.S.M. The committee was composed of L. A. Lanning, Chief Metallurgist, New Departure Mfg. Co., Bristol, Conn., and Dr. R. W. Woodward, Metallurgist, Underwood Elliott Fisher Co., Hartford, Conn.

not be allowed to remain in the solution longer than 5-10 sec., because with this method a thick plate of copper will fall off. The solution is made as follows:

Water	78%
Copper Sulphate	20%
Sulphuric Acid	2%

This method will prevent carburization for short periods. A dip plate is now on the market which is more satisfactory.

7. Electrodeposited Copper—The most widely used method, where production warrants the expense of installation and operation, is that of copper plating by electrolytic methods. Copper plating is effective with many carburizing compounds. With certain compounds copper does not prevent carbon penetration. Apparently the energizer used in the compound is the determining factor in the utility of copper plating as a preventative, because certain energizers will attack and remove the copper.

There is considerable difficulty in depositing the copper plate in recesses.

Two methods may be employed in using the copper plate method:

1. *Plate the Entire Piece*—The entire piece is plated and then the copper is removed by machining or grinding from the portion which is to be hardened.

2. *Selective Plating*—By the use of suitable protective paints, selective copper plating can be obtained which will leave the parts desired hard free from copper.

The usual method is to use japan. The japan is painted on the proper parts and is then baked, being careful not to use too high a baking temperature, 350-400°F. is about the upper limit. After the baking, the plating may be carried out in the usual manner. A second and, perhaps, more simple method of painting with a suitable lacquer paint successfully protects the parts from the copper plate. Care must be used in the choice of lacquers, as many will strip off during the plating operation. The plate does not form on the covered surfaces. In the carburizing operation the japan or lacquer burns off, permitting the gasses of the carburizing operation to penetrate the areas desired hard.

The copper plating operation is standard in every way. The chief requirement is to produce a fine grained, continuous plate. This is done successfully by means of the cyanide bath process, using a solution of sodium cyanide and copper cyanide. Potassium cyanide may be used, but is much more expensive and does not yield results commensurate with the cost.

A suggested plating bath is as follows:

Water	100 gal.
Copper cyanide	20 lb.
Sodium cyanide	28 lb.
Anhydrous sodium carbonate	12 lb.
Sodium thiosulphate (hypo)	1½ oz.

These salts are dissolved directly in the water. Ordinarily the only additions required are sodium cyanide and brightener (hypo). For control purposes the free sodium cyanide should be kept between 0.75 and 1.25 oz. per gal.

The temperature of the plating bath should be maintained between 75 and 105°F. with corresponding current density range of 5-15 amperes per sq. ft. The lower temperatures produce the finest grain size of the deposited copper but for economic reasons the higher temperatures with accompanying greater current density should be used as far as possible provided adequate protection against carbon penetration is obtained.

Precautions—There are certain precautions which must be observed for successful plating and selective carburizing which are briefly as follows:

1. The work must be thoroughly cleaned before japanning. Any oil or grease under the japan causes the japan to loosen during the baking process, which will cause soft spots by allowing the copper to plate under the japan.

2. Before the plating operation, the work must be chemically clean. This is usually accomplished by means of first dipping in a metal cleaning solution, washing in water, dipping in weak hydrochloric acid, washing in water, dipping in a cyanide solution and again washing. This seems to be an elaborate preparation, but if complete protection is to be assured, it is necessary.

3. Care must also be taken to assure that the bath is of the proper strength to give a solid, continuous plate.

4. If any of the parts to be carburized have white or red lead on them, they should not be carburized with copper plated parts, because this will cause the copper to creep over portions of the work desired hard.

5. The thickness of the copper plate necessary for protection depends on a number of factors, such as the plating method used, time of carburizing, and the carburizing temperature. However, for satisfactory protection with most carburizing work a minimum plate of 0.0003 in. should be maintained.

The above methods for obtaining selective carburizing are successful under certain conditions, and their use depends largely upon local conditions. The details of each method must also be developed according to the conditions in the particular plant involved and the type of work to be carburized.

The data given are to be considered as a guide and assistance in accomplishing the desired results.

Nitriding

By Dr. V. O. Homerberg*

Introduction—The nitrogen case hardening process, which is termed "nitriding," consists in subjecting the machined and preferably heat treated articles to the action of a nitrogenous medium, commonly ammonia gas, under certain conditions whereby surface hardness is imparted to the material without necessitating any further treatment. Wear resistance, retention of hardness at elevated temperature, and resistance to certain types of corrosion are other properties imparted to the steel by nitriding.

Of the elements investigated, Dr. Fry found that aluminum ranked first as to the amount of nitrogen with which it combined as well as the stability of the aluminum nitride formed. This compound showed no loss in nitrogen even when heated at 1830°F. Other elements, which formed nitrides with high nitrogen contents include chromium, vanadium, titanium, tungsten, molybdenum, and manganese.

Nitriding Steels—The compositions of the most commonly used nitriding steels are as follows:

	N 125 (Type H)	N 125N* (Type H with Nickel)	N 135 (Type G)	N 135 Modified*	N 230
Carbon	0.20-0.30	0.20-0.27	0.30-0.40	0.38-0.45	0.25-0.35
Manganese	0.40-0.60	0.40-0.70	0.40-0.60	0.40-0.70	0.40-0.60
Silicon	0.20-0.30		0.20-0.30		0.20-0.30
Aluminum	0.90-1.40	1.10-1.40	0.90-1.40	0.95-1.35	1.00-1.50
Chromium	0.90-1.40	1.00-1.30	1.00-1.40	1.40-1.80	
Molybdenum	0.15-0.25	0.20-0.30	0.15-0.25	0.30-0.45	0.60-1.00
Nickel		3.25-3.75			

*Aircraft specifications.

‡"N" preceding a number indicates nitralloy steels.

Special Steels—The nitriding of steels containing principally combinations of chromium, molybdenum, and vanadium have been studied by several investigators.^{2, 4, 5} The results of Sylvester and Whiteside are given in Table I.

Nickel Nitriding Steels—French and Homerberg³ have studied the role of nickel in nitriding steels. Its effects are to strengthen and toughen the case with moderate decrease in case hardness. It strengthens and hardens the core and thereby provides better support to the case. It develops dispersion hardening in steels containing appreciable proportions of aluminum, by means of which articles may automatically acquire higher core strength and elastic properties during nitriding.

*Associate Professor of Physical Metallurgy, Massachusetts Institute of Technology, Cambridge, Mass., and Technical Director, Nitralloy Corp., New York.

Steel N 125N was oil quenched from 1650°F. followed by tempering at 1200°F. The core properties are as follows:

	Before Nitriding	After Nitriding

Brinell hardness no.....	277	415

High Sulphur and Selenium Nitriding Steels—A high sulphur nitriding steel is used for free machining when maximum impact properties are unnecessary. Fig. 1 shows the properties of a steel low in sulphur and one with high sulphur. Selenium is rapidly displacing sulphur for the purpose of promoting machinability.

A typical composition of such a steel is as follows: Carbon 0.30-0.40; manganese 0.50-1.10; silicon 0.30 max.; aluminum 0.75-1.50; chromium 1.00-1.50; molybdenum 0.15-0.25; sulphur 0.06 max.; selenium 0.15-0.25.

Nitriding of Austenitic Steels

—The austenitic steels investigated by Jones¹ were of the nickel, chromium-nickel, chromium-nickel-tungsten, manganese and nickel-manganese types. A temperature of 930-950°F. with a nitriding period of 90 hr. was employed. With some steels, modifications of the usual process were made, such as a variation in the ammonia dissociation, nitriding at a higher pressure, and changing the character of the surface of the steels preceding the nitriding treatment by pickling in acid or by copper plating.

He found that the chromium-nickel austenitic steels did not harden consistently until the

Fig. 1—Physical properties of high and low sulphur nitriding steels.

protective oxide surface film was removed. It was found that the oxide film reformed in local areas on the surface of some of the steels and, after nitriding, showed a dull exterior where the steel had hardened and a shiny area where it had not hardened.

The nitriding alloy most commonly used in this country has the following approximate composition: Carbon 0.45%; nickel 14.0%; chromium 14.0%; tungsten 2.5%; and molybdenum 0.30%. The usual practice is to treat with 50% hydrochloric acid and then nitride at 1000°F. for 50 hr.

Proper Condition of Steel for Nitriding—The nitriding steels do not warp or distort to any appreciable extent provided the internal stresses resulting from machining and heat treating are removed before nitriding. The steel should possess a sorbitic structure prior to case hardening with ammonia gas. The steel is generally purchased in the heat treated condition, unless forgings are to be made.

A sufficient amount of the heat treated stock must be removed to eliminate all traces of decarburization. Also, a reheating to a sufficiently high temperature (generally 1200-1300°F.) should be performed in order to remove stresses that are produced during the rough machining. This reheating is generally applied before the final machining or grinding operation.

A forging temperature of 1950-2200°F. is commonly used. Quenching in a suitable medium followed by tempering at 1150-1350°F. is common practice for producing a sorbitic structure suitable for machining and nitriding. In the case of the annealed forgings, they should be rough machined, then heat treated so as to produce a sorbitic structure, after which the machining or grinding is completed. Enough stock should be left for this final operation to insure the complete removal of the decarburized layer that is produced during the heat treating operation.

Mechanical Properties—The mechanical properties of several of these nitriding steels are given in Table II. Standard specimens (0.505 in. dia. and 2 in. gage length) were used for the tensile tests.

^aBars for both steels were water quenched from 1725°F.

The Nitriding Process—The nitriding process consists in subjecting the articles to the action of ammonia gas at temperatures ranging from 930-1200°F. Various nitriding cycles have been recommended by several investigators,^{9, 10, 11, 12, 13} but the range most commonly used is 950-1000°F.

Nitriding Equipment—Electric, gas, and oil fired furnaces are suitable and must maintain uniform temperature in the nitriding container. Special nitriding furnaces have been described by Roth,¹⁴ Lapelle,¹⁵ and Cowan.¹⁶

A batch type furnace and the nitriding equipment used are shown in Fig. 2.

Ammonia Gas—

The tank of ammonia must be placed in such a position that the bent tube inside the tank has its open end in the gaseous atmosphere and does not dip into the liquid ammonia. The use of a suitable needle valve insures the control of a steady and even flow of gas.

Although anhydrous ammonia is a commercial product, the final traces of water, if present, can be removed by passing the gas through a tower containing lime. The inlet and the outlet tubes are made of nickel and the articles in the box are supported preferably on nickel or nickel alloy screens. The inlet tube extends along the bottom of the box to the back while the outlet tube is at the front and near the top of the box. Pyrometers are inserted into both the container and the furnace. The gas mixture from the container passes through a wash bottle to indicate the back pressure, which should be about 1-2 in., as well as the rate of flow of the gas, and finally passes into the atmosphere or is washed into the drain in the sink by means of a suitable baffle.

Ammonia gas decomposes to a certain extent into nitrogen and hydrogen according to the following reaction: $2\text{NH}_3 \rightleftharpoons 2\text{N} + 3\text{H}_2$. Nitrogen, which is very active at the moment of the decomposition of the gas, combines to a certain extent with the alloying elements in the steel to form nitrides. These nitrides, which are in a fine state of dispersion in the case, impart extreme hardness to the surface of the steel, a hardness which gradually decreases inwardly until it corresponds to that of the core.

The gas mixture leaving the furnace consists of hydrogen, nitrogen, and undissociated ammonia. The ammonia gas is soluble in water whereas the hydrogen and the nitrogen are insoluble. Advantage is taken of this fact in the determination of the extent of the ammonia dissociation during the nitriding operation. The special pipette shown in Fig. 3 is used for making this determination. The dissociation is generally maintained at approximately 30%.

At the time that a determination of the extent of the ammonia dissociation is to be made, the stopcocks at "C" and "E" are closed while "D" is open and the stopcock at "A" is turned so as to admit the gas mixture from the container into the graduated chamber. After the air has been expelled, stopcock "D" is closed and "A" is turned so as to by-pass the gas mixture. Reservoir "G" is filled with water, after which the stopcock "E" is opened to admit the water into the graduated chamber. The water immediately hydrogen and nitrogen. The water solution should reach approximately the 30 cc. absorbs the ammonia and the atmosphere above this solution contains the insoluble

Fig. 2.—Nitriding furnace and equipment.

Fig. 3.—Pipette for determining ammonia dissociation.

mark, indicating 30% of dissociation. If it is much above this value the flow should be increased, while if much below the degree of dissociation can be increased by decreasing the flow of the gas by means of the needle valve.

Nitriding Containers—Unfortunately, low carbon steel absorbs nitrogen and the inside surface of containers becomes embrittled. Besides the embrittlement, it is also believed that the nitrided surface has a harmful influence in catalyzing the ammonia in contact with it and thereby preventing the proper nitriding of the articles. It is the atomic nitrogen in immediate contact with the steel parts that is responsible for the nitriding.

Enameled low carbon steel containers have been used successfully. Such a coating is easily chipped and may spall at the nitriding temperature because of the pressure of the gases within the steel. Careful handling of the articles to be nitrided must be exercised in order not to chip or crack the enamel.

High chromium and high nickel alloy containers (welded) are being used successfully with the approximate compositions: Chromium 12%; nickel 80%, or chromium 25%; nickel 20%.

Methods of Sealing Containers—Various sealing methods have been discussed by Sergeson¹¹ and Deal as shown in Fig. 4.

Depth Hardness Data—Typical depth hardness curves for several nitriding steels are shown in Fig. 5a and 5b.

The hardness testing machines that are most commonly used for testing the hardness of nitrided steels are the Rockwell Superficial hardness tester and the Vickers.

Growth on Nitriding—Articles increase slightly in size after nitriding. This growth is dependent mainly on the temperature and the time of nitriding. Absence of decarburization is of vital importance as the

Fig. 4—Methods of sealing containers.

Fig. 5a—Depth-hardness curves. All steels were quenched in water from 1725°F. and tempered at 1000°F. nitrided at 975°F. for 48 hr.

Fig. 5b—Depth-hardness curves for same steels and treatments as Fig. 5a, but in addition a depth-hardness curve for selenium nitriding steel C 0.34%, Cr 1.36%, S 0.033%, Al 1.13%, Mo 0.22%, Se 0.28%. Nitrided at 975°F. for 48 hr.

nitriding of a decarburized surface not only produces excessive growth but also produces a brittle case. The amount of growth is constant under the same conditions, so that after it has once been determined for a given material it can be allowed for in the final machining, grinding, or lapping. An increase in diameter of 0.002 in. in a specimen having a case depth of 0.030 in. is a fair example of this growth. Cunningham and Ashbury¹¹ found that the growth on a 1 in. dia. solid bar that had been nitrided for 80 hr. at 930-940°F. varied from 0.0012-0.0014 in. A bar of the same dia. but bored with a $\frac{1}{2}$ in. dia. hole expanded the same extent on the outside dia., but was reduced to the extent of 0.001 in. on the inside dia. A third bar bored with a $\frac{3}{8}$ in. dia. hole, leaving only $\frac{1}{8}$ in. wall, expanded approximately 0.005 in. on the outside dia. and 0.0012 in. on the internal diameter. This variation of internal growth is apparently controlled by the thickness of the surrounding metal. Undoubtedly, the tendency of the bore to expand increases as the thickness of the wall diminishes.

Hubbard and Robinson determined the change in dimensions of hollow cylinders with varying wall thickness. The outside dia. of the specimens was 2½ in. with wall thicknesses of $\frac{1}{8}$, $\frac{1}{4}$ and up to 1¼ in. at $\frac{1}{8}$ in. intervals.

The specimens were rough machined after quenching from 1725°F. followed by tempering at 1300°F. for three hours. After leaving $\frac{1}{8}$ in. for final grinding, the hollow cylinders were heated to 1000°F. for 3 hr. to relieve stresses and then ground to final dimensions. The specimens were nitrided at 975°F. for 72 hr. The results of this investigation are shown in Fig. 6.

Walsted¹² states* that the growth of the diameter of a solid cylinder on nitriding is undoubtedly dependent on case depth and will be the same whatever the original diameter of the cylinder. Homberg and Walsted¹³ have called attention to the "corner effect" that occurs on nitrided parts possessing sharp corners. The growth on all surfaces combines at the corners to form projections containing a high nitrogen content with no supporting core. This portion of the case is brittle and likely to chip. Such a condition should be avoided by providing rounded corners.

Protection Against Nitriding—The most efficacious protective agent against nitriding is tin or a solder containing 80 parts of lead and 20 parts of tin. Although tin and the alloy of lead and tin melt at a lower temperature than that used in nitriding, ample protection is provided by the thin layer that is held to the article by surface tension. Too much of the protective agent may cause the excess amount to drop onto articles at points where protection is not desired. A liquid flux is used which is made by adding zinc to a solution containing 500 cc. hydrochloric acid, 250 cc. water and 15 g. of ammonium chloride until no further action takes place. Parts to be tinned should be entirely free from rust or scale.

For protection of the end of a part, clean the part to be protected, apply flux and dip into molten tin or solder to the depth to be protected. Remove excess tin or solder with wire brush. For protection of the mid-section of a part, protect ends to be hardened with fireproof varnish (such as Bakelite varnish), apply flux and dip piece into molten metal to required depth. Remove varnish and excess metal with wire brush. For protection of small surface or keyways, apply flux to area, then apply protective agent with a soldering iron.

Tin plating is an excellent means for providing protection. A plating of 0.0007 in. will protect the parts and will not run. Nickel plating also gives satisfactory results. A thickness of 0.0005 is sufficient.

Painting with either a mixture of glycerine and tin oxide or shellac and pure tin oxide is also used although complete protection is not always obtained with

Fig. 6—Growth in rings or cylinders of N 135 due to nitriding.

*This statement is true only if the general structure of the part is the same. A large forging, in which it is difficult to obtain a fine grained sorbitic structure, will show a greater growth than a small part in which the structure is uniformly fine grained sorbite.

these materials. A paste containing lead and tin in a fine condition in a suitable vehicle is also used. Powdered tin in clear Feroleum provides a satisfactory paint.

Distortion—Parts of uniform section and parts which have been treated so that no machining stresses are present, can be nitrided without appreciable distortion. The removal of the stresses produced by rough machining is accomplished by reheating to 1100-1200°F. before final machining or grinding. Usually a period of 1-4 hr. at temperature is sufficient. Slight distortion may occur in other sections because of unequal growth.¹³

Thin strips, after protecting one of the sides against nitriding, bow with the nitrided part on the convex side. The extent of the bowing increases as the time of nitriding is lengthened.

Slightly distorted parts can be straightened both cold and hot, but the latter is preferred. Such straightening, especially when it is done cold, should be performed with caution in order not to crack the case. Any cracks that may be produced will lead to fatigue failures and also cause failure to withstand corrosion. Since no softening of the case takes place on heating at 1200°F. for a short time, it is entirely safe to heat to this temperature for straightening.

The complete removal of internal stresses before nitriding and the proper placing of the parts in the nitriding container will greatly remove the possibility of warping or distortion.

Surface Defects—If the decarburized surface is not all removed before nitriding, the case will spall. Parts that are coated with rolling or forging scale necessitate the removal of $\frac{1}{32}$ - $\frac{1}{16}$ in. of material to thoroughly eliminate the decarburized layer.

Softening and Denitriding—As there are occasions when it is desirable to soften nitrided parts for the purpose of making changes in design, it is frequently desirable to soften the nitride case. Merten¹⁴ recommends the heating of the nitrided parts in a fused bath consisting of a mixture of 50% each of sodium and potassium chlorides at a temperature of 1500°F. whereby a decomposition of the nitrides takes place. Sergeson and Deal¹⁵ state that softening can be performed by annealing at 1800°F. but that renitriding to obtain the original hardness cannot be achieved. Cunningham and Ashbury¹⁶ state that decarburization accompanies denitriding and that the original hardness is not obtainable on renitriding. The complete removal of the softened layer is necessary before the renitriding can be performed with success. Such a procedure obviously precludes the use of these softening processes on finished articles.

Fig 7—Hardness comparison of nitrided and carburized cases at room and elevated temperatures.

Retention of Hardness on Nitride Case—The retention of hardness of the nitride case and the softening of the case of a case hardened chromium-nickel steel are shown in Fig. 7.

Tensile Properties of Nitrided Steels—Since the nitride case represents only a small portion of the cross section of a tensile test piece, it has little effect on the tensile strength. Table IV shows the results of tests conducted by Homerberg and Walsted.²² Tensile specimens were quenched in oil from 1650°F., and tempered as shown.

Table IV
Mechanical Properties of Steel N 135, Nitrided*

Tempering Temp. °F.	Condition Tested	Tensile Strength, psi.	Yield Point, psi.	Elong. in 2 in., %	Reduction of Area, %	Charpy Impact, ft.-lb.
1000	Tempered	182,000	165,000	15	50	22
1000	Nitrided	171,000	139,000	6	13	14
1100	Tempered	156,000	138,000	18	57	35
1100	Nitrided	159,000	129,000	5	16	18
1200	Tempered	138,000	120,000	20	60	44
1200	Nitrided	138,000	110,000	4	17	21
1300	Tempered	121,000	103,000	23	62	55
1300	Nitrided	123,000	98,000	8	20	24

*Tensile specimens were nitrided 90 hr. at 900°F.

Coefficient of Linear Expansion—The Ludlum Steel Co. reports the following data for the coefficient of linear expansion for steel N 135, and the Firth-Brown Research Laboratory, the coefficient of expansion for the case.

Temp. °C.	Centimeters per °C.		Temp. °C.	Case	cm. per °C.
	Unnitrided	Nitrided			
0-100	0.00001184	0.00001214	20-100		0.0000107
0-200	0.00001188	0.00001218	20-200		0.0000113
0-300	0.00001192	0.00001222	20-300		0.0000118
0-400	0.00001196	0.00001226	20-400		0.0000123
0-500	0.0000120	0.0000123	20-500		0.0000129

The coefficient of linear expansion for a 0.25% carbon steel from 0-200°C. is 0.0000115 cm. per °C.

Fatigue Properties of Nitrided Steels—Since nitrided steels are frequently used in applications where they are subjected to repeated stress, the effect of nitriding on the endurance properties is of considerable importance. Nitriding increases the endurance range as determined by reversed bending.

Sutton has summarized the results of rotating beam fatigue tests that were performed by a number of investigators. They are given in Table V.

In fatigue tests conducted by Sutton, an examination of the fractures of Wöhler test pieces indicated that the cracks commenced at a point near the junction of the case and the core but within the core material. His results indicate that the fatigue fracture of a nitrided specimen results when the stress exceeds the fatigue limit of the core at a point near the junction of the case and the core. Ordinarily, the permissible loads on nitrided specimens are therefore limited by the fatigue properties of the core material.

Table V
Summary of Results of Rotating Beam Fatigue Tests

[illegible]

The effect of scratches and notches was studied by Hengstenberg and Malländer. Since fatigue cracks in nitrided parts do not commence at the surface, small surface defects (notches, threads and scratches) are not so highly important as in other steels. Hengstenberg⁷ and Malländer notched a nitrided specimen to a depth of .0004 in. by grinding. In a rotating beam type of fatigue test this specimen remained unbroken after being subjected to test at a stress range of 71,700 psi., but failed at 88,500 at an undamaged place, the origin of the fracture lying in the

core. Further experiments showed that a turned notch .0004 in. deep that was cut before nitriding had no effect on the fatigue strength while the same notch on an unnitrided specimen reduced the fatigue strength by 45%.

The results of fatigue tests on a nitrided and unnitrided steel with different types of surfaces are given in Table VI.

Johnson and Oberg²³ found that the V notches in the case did not reduce the fatigue limit provided that the notches were cut before nitriding. They also found that scratches were without effect until their depth was about 70% of the depth of the case.

Table VI
Results of Surface Condition Fatigue Tests

Condition	Tensile Strength, psi.	Fatigue Strength, psi. (Rotating Beam)		
		Polished Smooth	Sharply Notched ^a	Fillet ^b 0.04 in.
Not nitrided	138,900	73,900	40,300-41,400	45,900-47,000
Nitrided for 60 hr.	87,400-88,500	87,400-88,500 ^c	87,400-88,500

^a0.004 in. deep, as sharp as possible; notched before nitriding.
^bAt the joint of test length (0.30 in. dia.) to ends (0.48 in. dia.). Samples finish machined before nitriding.
^cSpecimens did not break at notch.

Fuller²⁴ showed that the high endurance value for nitrided steels at elevated temperatures could be expected to be retained up to 800-1000°F. because the hardness and strength values of the case are not materially affected at these temperatures, (see references 1, 26, 27, and 28).

McAdam²⁵ tested a steel containing 0.36% carbon, 2.03% aluminum, and 1.62% chromium. It was oil quenched from 1750°F. and tempered at 1200°F. All the grinding and polishing were done prior to the nitriding. The resistance to fatigue corrosion of this steel was superior to stainless, chromium-nickel, and chromium-vanadium steels, when tested in carbonated and salt waters.

Tensile Properties at Elevated Temperatures—Homerberg and Walsted²⁶ oil quenched a nitriding steel from 1650°F., tempered at 1000°F. and then nitrided 90 hr. at 900°F. The results obtained at high temperatures are given in Table VII.

Table VII
Effect of Temperature on Properties of Nitrided N 135

Testing Temp. °F.	Tensile Strength, psi.	Elongation in 2 in., %	Reduction of Area, %
800	134,000	6.5	30.5
900	124,000	9.5	31.0
1000	98,000	15.5	44.5
1100	42,000		
1200	39,000		
1300	28,000		
1400	20,000		

Creep Tests on Nitrided Steel—Malcolm²⁷ tested nitrided steel at 1000°F. under a load of 10,180 psi. After 4,000 hr. the extension amounted to 0.002 in. per in. with no further extension during an additional 5,000 hr.

Abrasion and Wear Resistance of Nitrided Steels—Malcolm²⁷ tested nitrided and stainless steels in a wear testing machine under a pressure of 200 lb. The nitrided steel withstood 100,000 strokes without scoring and with no appreciable wear, whereas the stainless steel was badly abraded after 1,000 strokes.

Homerberg and Walsted²⁶ have reported the results of wear tests in which nitrided steel was tested against itself and against a number of other materials without lubrication. The two materials that showed excellent results when operated against nitrided steel were the nitrided steel itself and a bronze of the following composition: Copper 80.2; tin 11.5; nickel 5.5; and zinc 2.8%.

Leaded and graphitic bronzes are generally used as bushings to run against nitrided steels. A bronze containing 80 copper, 10 tin and 10 lead is suitable for the purpose.

Corrosion Resistance of Nitrided Steel—Sergeson and Deal¹¹ have reported the corrosion resisting properties of nitriding steels after nitriding for 90 hr. at 975°F. Their conclusions are as follows:

1. Nitrided steel is not adapted for use in mineral acids, such as sulphuric and hydrochloric.
2. Nitrided steel is extremely resistant to alkali, atmosphere, crude oil, natural gas combustion products, tap water, and still salt water.
3. It is slightly attacked in aerated salt water and under alternate wetting with salt water and drying.

Malcolm¹² has reported that nitrided steel shows excellent resistance to oxidation and corrosion under the action of superheated steam.

It should be clearly emphasized that the maximum resistance to corrosion is shown by the outermost layer of the nitrided case. Therefore, it is of importance that nitrided specimens should not be ground after the nitriding operation if maximum resistance to corrosion is desired.

Welding of the Nitriding Steels—Homerberg¹³ and Walsted have welded nitrided steels by the atomic hydrogen process and by flash welding. A welding rod of the same material was used in the atomic hydrogen process. No appreciable difference between hardness at the weld and away from it was shown after nitriding.

Determination of Case Toughness of Nitrided Steel—The character of the impression produced by the various hardness testing machines is indicative of the toughness of the case. If the impression is free from spalled edges the nitride case will be tougher than one in which the edges are not well defined.²

Precautions and Recommendations

1. To insure the best nitriding results, the steel should be heat treated so as to possess a uniformly sorbitic structure.
2. Before nitriding the steel must be free from decarburization.
3. If freedom from distortion is of paramount importance, the internal stresses produced by machining or heat treating should be removed before nitriding by heating to a temperature of 1000-1300°F.
4. Since some growth takes place on nitriding, this should either be allowed for in the final machining or grinding operation prior to nitriding or removed by lapping or by careful grinding. However, the removal of only a slight amount of the nitride case is permissible.
5. If maximum resistance to corrosion is desired, the parts should be used as they come from the nitriding container.
6. Nitrided steels of the nitralloy type should not be used where resistance to the corrosion of mineral acids is encountered or where resistance to sharp abrasive particles at high velocities is required, as in sand nozzles.
7. If straightening is required after nitriding, it should be done hot at 1200°F., although some straightening may be done cold.
8. If maximum hardness and maximum resistance to impact are desired and the question of maximum corrosion resistance is not of vital importance, the removal of 0.001-0.002 inch of the nitrided case is desirable. The amount to be removed depends upon the original case depth. This operation will remove the more brittle and somewhat softer surface layer.
9. If nitrided articles exhibit a shiny gray surface after their removal from the container, the results should be viewed with suspicion. Invariably, the case will be shallow and below normal hardness. The articles should have a matte gray appearance, although a slight discoloration does not indicate faulty nitriding. A slight vacuum may be created within the container when the furnace is shut off and if a small amount of air enters through the gasket, the articles may show various hues such as pink, blue, or light brown. Increasing the flow of ammonia at this stage or nitriding in the presence of copper turnings will frequently prevent this discoloration. The opening of the container at too high a temperature will also cause surface discoloration.
10. Specimens that can be checked for hardness and depth of case should be included with every charge.
11. Applications requiring a high core hardness to support the case when high compressive stresses are present require nitriding steels of special analyses.
12. Although special nitriding furnaces are desirable, such equipment is not absolutely necessary. In most instances these special furnaces are constructed so that they can be used for general heat treating purposes when not used for nitriding. The most essential point is that a furnace must maintain a uniform temperature within the nitriding container.

Aluminum Impregnation

(Calorizing)

By B. J. Sayles*

Definition—Calorizing is a trade name for an aluminizing process for alloying the surface of carbon or alloy steel with aluminum by diffusion. The depth to which the action penetrates varies from 0.005-0.040 in., but on thin articles the usual depth is 0.025-0.030 in., the surface layer of iron-aluminum alloy, usually containing approximately 25% aluminum.

Methods—There are several distinct processes for performing the aluminizing operation as follows:

Old Style Powder Calorizing—This practice was in general commercial use until 1935. The articles were hermetically sealed in revolving retorts packed in a powder compound in which the active ingredient was powdered aluminum. Time of treatment was usually four to six hours at a temperature of 1550-1700°F. The resulting iron-aluminum surface alloy was of a depth of 0.001-0.006 in. and contained about 60% aluminum.

The surface alloy possessed excellent heat enduring and sulphur corrosion resisting qualities but, by reason of the high aluminum content, was brittle and inclined to spall from the surface whenever the article was subjected to mechanical abuse such as the application of a rotary tube cleaner.

Modern Powder Calorizing—Since 1935 this process† has continued with the foregoing method for securing a primary iron-aluminum alloy, but subsequently the work is removed from the rotating retort and heat treated for periods of 12-48 hours at temperatures from 1500-1800°F. to cause the aluminum to penetrate by diffusion to depths ranging from 0.025-0.040 in. Since no compound is in contact with the work during the heat treatment, the aluminum content at the surface of the article is reduced to 25% or less. This is ample for heat enduring and corrosion resisting purposes. With this aluminum content the surface alloy obtains the qualities of toughness and ductility not to be found in the older process.

Pack Calorizing—This consists of packing the work in hermetically sealed stationary boxes with the powdered aluminum compound. The process requires from 6-24 hr. at temperatures ranging from 1500-1800°F. Since it is a combined aluminizing and diffusion heat treatment, no further treatment is needed when the work is removed from the container. The process is of particular value for handling articles of light gage or irregular shape which might be damaged by processing in rotating retorts.

Dip Calorizing—The work, suitably cleaned and fluxed, is immersed in molten aluminum in a manner similar to that employed for hot dip galvanizing. This results in a superimposed coat of practically pure aluminum with slight formation of an iron-aluminum alloy at the face of the parent metal. Under suitable conditions the thickness of this alloy layer may be increased by subjecting the material to heat treatment, though a primary coat of pure aluminum can not be diffused to give surface alloys of relatively low aluminum content.

The process is of particular value where the corrosion resistance of pure aluminum is desired combined with the strength of the underlying steel.

Flank Process—This is essentially a dip Calorizing process for wire but is distinguished by maintaining the steel to be treated in hydrogen atmosphere after it leaves the pickle bath and before immersion in the molten aluminum bath.

While wire readily lends itself to the passage through a hydrogen tunnel between the pickle and aluminum baths, the process may be impractical when handling a wide range of various sizes and shapes.

Martin Process—In this process the surface alloy of iron-aluminum is formed by treating the metal in aluminum chloride vapor at high temperature. It is reported that the surface alloy thus obtained is shallow compared to the other processes.

*Calorizing Co., Pittsburgh, Pa. Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

†U. S. Patent No. 1,988,217.

Spray Gun Process—For a description of the process for spraying molten aluminum see page 1115.

Oxidation Resistance—Calorizing protects steel from oxidation and flue gas corrosion at high temperature by the formation of a film of aluminum oxide on the surface. This film is self-replacing as long as any appreciable amount of aluminum remains at the surface. At temperatures under 1400°F., the life of a Calorized part is a matter of years. Calorized parts, however, are used up to temperatures of 1700°F. for purposes where the life of the part, such as a heat treating pot, is usually long enough to justify the higher cost as compared to that of carbon steel.

Table I gives the relative oxidation resistance of some steels before and after calorizing.

Sulphur Corrosion Resistance—The type of corrosion resistance of commercial importance is immunity to the attack of various kinds of sulphurous gases—H₂S, SO₂, SO₃—found in furnace flue gases at high temperature. Calorized articles may, therefore, be used in furnaces which employ high sulphur fuels. Calorizing has wide acceptance in oil refineries and contact sulphuric acid converter heat exchangers. It is rapidly attacked, however, by aqueous solutions of mineral acids and, hence, not suitable at the low temperature end of furnace ducts where condensation of water vapor in the flue gases is likely to cause formation of sulphurous acid.

Table II gives results of sulphur corrosion of some steels before and after Calorizing. The test was conducted in a muffle type furnace with hydrogen sulphide flowing continuously at atmospheric pressure.

High Temperature Creep Strength—The Calorizing process, by protecting the base metal from loss of cross section due to oxidation, extends the useful, high temperature working range of many low priced steels which do not possess oxidation resistance. As an example, a killed carbon steel containing C 0.08-0.18, Mn 0.30-0.60, and Si 0.50 required before Calorizing, 1400 psi. unit stress to produce 1% creep in 10,000 hr. at 1100°F., but after Calorizing this same steel under the same condition of test required 2,050 psi.

General Physical Properties—The iron-aluminum surface alloy is hard, but is sufficiently tough to exhibit about 5.0% elongation before development of surface cracks. This enables the surface alloy to bend with the steel when hot and the product is not subject to cracks under stresses within commercial limits.

Uses—Pots for salt, cyanide, and lead preferably operating at a bath temperature of not over 1550°F.; bolts to 1400°F. Tubes for air heaters, radiant steam superheaters, oil and gas polymerization. Furnace parts to 1400°F., glass lehrs and non-ferrous heating furnaces.

Fabrication—Except with light thicknesses of surface alloy of low aluminum content, such as employed on automobile exhaust pipes, cold fabrication of Calorized steel is not practical. Usually bending and forming must be performed at bright red heat, but unless the bending radii are liberal, cracking may occur. The Calorized steel will stand about 5% elongation before surface fissures appear.

Chromium Impregnation (Chromizing)

By F. C. Kelley*

The Process—The process consists of packing the material to be treated in a mixture of powdered alumina and chromium. Alumina is used to prevent the sintering of the powdered chromium into a solid mass. The amount of each material used may be varied, but a satisfactory mixture consists of 45% of dry alumina and 55% of chromium by weight. The material is usually packed in a tube or container of iron and then heated to 2375-2550°F. in hydrogen for three or four hours. The time may be varied according to the penetration and concentration of chromium desired.

The Atmosphere—A protective atmosphere like hydrogen is absolutely necessary to protect the chromium from oxidation and should be free from oxygen and water vapors. The chromium particles in contact with the material to be treated must be kept clean so diffusion may take place. The hydrogen should be of sufficient purity to reduce chromic oxide for this will preserve the chromium powder in the metallic state and prevent loss by oxidation. The hydrogen may be passed directly into the iron container holding the charge. The container should be provided with a vent to allow circulation of the pure hydrogen.

The atmosphere of the furnace may be commercial hydrogen with enough water and oxygen removed to protect the molybdenum winding from oxidation.

The Furnace—The temperatures used in this process demand a furnace capable of maintaining a high temperature over a long period. An electric furnace provided with a molybdenum or tungsten winding as the heating unit is used. A satisfactory type consists of an alundum tube wound with molybdenum wire. The tube is placed in a suitable furnace casing and surrounded with alumina powder which acts as a heat insulating material. The furnace casing should be tight to prevent the loss of hydrogen and the diffusion of air into it.

The Material—The material best suited for chromizing is a low carbon steel having a carbon content of 0.10-0.20%. Steels of higher carbon content may be used if the surface is first decarburized as by heating in hydrogen. Materials to be

chromized should have a clean surface so diffusion may take place freely. Machined parts should be free from oil, grease, or soap.

Structure of Coating—The layer of chromized material on the surface of iron treated by this process consists of large columnar grains. This structure is typical of many coatings formed on iron by diffusion processes. Elements such as aluminum, silicon, molybdenum, and tin diffusing with iron form coatings of similar structure.

Diffusion Rates—The penetration of the chromium with respect to time and temperature is best shown by curves in Fig. 1A and 1B.

Corrosion Resistance—Chromized iron has a high resistance to corrosion in salt spray, steam and under atmospheric conditions, and will stand up for long periods of time in 10% nitric acid without discoloring the solution. The chromium content of the diffused layer varies between 10 and 20%, according to the time and temperature of heating.

Other Methods—Becker, Hertel and Kaster have produced a chromium iron alloy by heating metallic chromium or ferrochromium and the iron to be chro-

Fig. 1A—Curve showing the change in penetration of chromium with the time at a temperature of 2375°F.

Fig. 1B—Effect of temperature upon the penetration of chromium for a period of 3 hours.

*Research Laboratory, General Electric Co., Schenectady. Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

mized in a tube at 1750-1800°F. Pure dry hydrogen is first passed through the tube on heating. When the desired temperature is reached the dry hydrogen is then passed through fuming hydrochloric acid over the metallic chromium and finally over the iron to be chromized. The CrCl_3 vapor formed by the reaction between the hydrochloric acid gas and the chromium exchanges its chromium atom for an iron atom when it comes in contact with the iron surface, forming an alloy with the same characteristic structure as chromized iron. The grain size of the iron unaffected by the chromium must be smaller in this process than in the powder process due to the difference in the temperatures used. The resulting coating has the same physical and chemical characteristics as the coating produced by the powder process. It can be worked cold and resists the attack of nitric acid at all temperatures.

Diffusion is slowed up considerably below 1650°F., while above 1800°F. the grain size is large.

W. M. Mitchell secured a United States patent on a process for coating the surface of a steel ingot with a chromium iron alloy. He coats the surface of a mold with chromium using sodium silicate as a binder. When hot metal is poured into the mold it alloys with the coating and produces a chromium iron alloy on the surface. The ingot can then be rolled into sheets with a high chromium alloy on the surfaces. Castings with a high chromium alloy on the surfaces can also be made in the same way.

A British patent was granted to M. Fiedler for a process of coating a metal with a chromium rich alloy which consists of electroplating chromium on the surface of steel and then passing the plated article through a high frequency field to raise its temperature where alloying occurs between the base metal and the chromium plate. By this process iron pipe can be chromium plated on the outside and then passed continuously through a high frequency coil to heat it to about 2200°F., where alloying takes place between the chromium plate and the iron underneath.

Folliet and Sainderichin of Paris, France, were granted a United States patent on a cementation mixture for treating ferrous articles, comprised of an oxide of chromium, 2-10% of a chloride of chromium, and a quantity of finely divided aluminum. The aluminum content depends upon the amount of oxygen in the metallic oxide used. The articles to be coated together with the mixture in which it is packed are contained in a closed vessel and heated to 1825-2375°F. The action of the aluminum and the chloride results in an alloy between the liberated chromium and iron. The depth of penetration depends upon the percentage of metal oxides and the time at the working temperature.

Application—Chromizing has been used to protect turbine buckets against corrosion and erosion. Containers used for copper brazing tungsten contacts have been chromized so the copper would not braze the contacts to the container. The hydrogen atmosphere used for copper brazing usually contains enough water vapor and oxygen to oxidize the chromium on the surface and thus prevents the copper from wetting it.

Any steel parts which have to withstand atmospheric corrosion or the attack of nitric acid may be chromized to give satisfactory resistance. The chromized surface layer is practically free from carbon, and no attack occurs due to carbide precipitation.

Zinc Impregnation

(Sherardizing)

By F. C. Kelley*

The original patent on this process was applied for in England on July 21, 1901, by Sherard Cowper-Cowles of London. The metallurgist of that time claimed that the zinc coating produced by this process was structureless but today we know that is not true.

Apparatus—The present day process is best carried out in tightly sealed drums to prevent as much oxidation of the zinc as possible. These drums are rotated in gas or oil fired furnaces to produce uniform coating of high density. Electrically heated drums having double walls properly insulated are also used. The electrical heating units are placed between the walls of the drum which is supplied with several containers made of coarse wire screen so that the charge in any container may be removed at any time. The drums in any case are not filled with powder. This allows the parts to be treated to rub against each other and the powder to change its position.

Sulphuric acid tanks or shot blasting apparatus is also necessary for cleaning the surfaces of material, the latter being preferable.

The Zinc Powder—The zinc dust should be as free from impurities as possible, especially from lead, although small amounts of silica or oxide of iron do not seem to be deleterious. Periodic chemical analysis is necessary, and on the basis of the results, the metallic zinc content is maintained between 80 and 92%, the remainder being zinc oxide and impurities.

One method used for the determination of zinc is the displacement of hydrogen from sulphuric acid. In this method the apparatus is carefully calibrated. The volume of gas liberated is corrected for temperature and pressure and also for the hydrogen evolved by iron and tin present in the powder.

Typical analyses of new and used dust are as follows:

	New Dust	Used Dust
Silica	Trace	0.43
Cu	0.01	Nil
Pb	0.99	0.81
Fe	0.39	1.16
Cd	Nil	Nil
Zn	97.98	84.50
ZnO	0.46	12.12
Total Zn	98.34	94.57

When new powder is used, it is first heated in the drums without any charge for a sufficient time to oxidize the powder so that the zinc content, when analyzed, comes within the specified range.

The used powder is analyzed frequently and new powder added when necessary to keep the zinc content above 80%.

It is necessary to remove the iron and iron oxide from the mixture by magnetic separation to maintain the uniform quality of the coating.

The particle size of the zinc powder, the analysis of which is given above, varies and the screen analysis is given below.

	Zinc, %
On 100 mesh	3.65
On 150 mesh	1.05
On 200 mesh	3.55
On 350 mesh	6.25
Through 350 mesh	84.50

Some of this zinc dust has a particle size as small as 1/40,000 to 1/50,000 of an inch.

Powder low in zinc (35%) gives a coating of sp.gr. 1 while that with a zinc content of 90% gives a coating of sp.gr. 6.75 when a temperature of 660-700°F. is used.

The powdered alloy of FeZn₁₀ has been used to a limited extent, but the temperature of heating must be higher than that for the powdered zinc.

*Research Laboratory, General Electric Co., Schenectady. Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

Sand was added to the powder in the early process to prevent caking at the higher temperatures and small amounts of carbon were added to limit the amount of oxidation of the zinc.

Temperature—The wide range of temperatures originally used gave widely varying results. Today the process is usually carried out within the temperature range of 660-700°F. which gives a satisfactory product. Lower temperatures result in a thinner zinc coating while higher temperatures give a coating with a greater iron content and not so resistant to the action of the atmosphere. The length of time required for sherardizing varies from 3-12 hr. depending upon the thickness of coating desired.

If the operating temperature is materially above 660-700°F. the coating is coarse and crystalline, but if much below this, the coating is relatively soft and porous. For the best coating it has been claimed that the charge should be heated as rapidly as possible to the temperature 660-700°F. In the case of the electrically heated drums this is done by the use of parallel series connections to the heater units.

The Coating—The color of the coating is gray. When the coating is cleaned by brushing or rubbing it has about the same color as pure zinc.

There is usually only one layer observed on the surface of the iron but by heating to higher temperatures a second layer is sometimes found. There has been some difference of opinion as to the composition of the single phase layer, some claiming it to be Fe Zn_7 , and others, Fe Zn_{10} . McCulloch found by heating iron foil in zinc dust for 45 days at 779°F. that the alloy formed contained about 6% of zinc. If he heated a similar piece of iron foil for two days at 689°F. he obtained about the same result. From these experiments McCulloch claimed the limit of the iron-zinc solid solution to be 6% of iron instead of the higher percentage usually shown in the constitution diagram. He gives 8-10% as the average iron content of good sherardized coatings. When the second layer appears it is much richer in iron, and Rawdon has suggested that it might be Fe Zn_4 .

All sherardized coatings are filled with minute cracks which are probably due to the large difference in expansion between the coating and the iron base.

The thickness of the coating produced in 3 hrs. at 660-700°F. is about 0.0025 in.

Fig. 1 shows a photomicrograph of an unetched specimen of sherardized iron with a light alloy coating of about 1.5 mils thickness. The fissures which show up so clearly are typical of all sherardized coatings.

The Cementation Process—Some have claimed that the coating is deposited from the vapor phase while others believe it is formed by contact between the metal and the powder.

Several years ago the author investigated the possibility of improving the process by carrying out the operation in a vacuum of 1 mm. pressure. It was found that there was little if any difference in the thickness or character of the coating if the charge was revolved when compared with samples produced in the regular way. This would seem to indicate that the coating was formed largely through contact of the powder with the iron. The vapor pressure of zinc is probably high enough to give a slight coating, but not enough to produce the thickness obtained in the regular process. Trood claimed that he obtained a much heavier coating in vacuum in a shorter length of time.

The fact that particles of iron oxide and silica are sometimes found imbedded in the coating supports the claim that the coating is formed by contact.

The Weathering of Sherardized Coatings—All sherardized coatings are anodic toward the iron with which they are in contact, but to a lesser degree than pure zinc on account of the iron which has diffused into them. Burgess found the potential for the alloyed coating was 0.20 to 0.25 volt against 0.50 volt for zinc. This accounts for the protective value of the zinc coatings.

The coatings low in iron content weather and gradually become dark and finally

Fig. 1—Sherardized iron—unetched.

almost black, but those with higher iron content become reddish due to the oxidation of the iron. The appearance of the red color does not necessarily mean that the iron underneath has been attacked. Those coatings high in iron however, do not resist the action of the atmosphere as well as those with lower iron content. The coatings high in iron will rust almost immediately in salt spray while those low in iron will stand up well. Those coatings which have 15-20% of iron break down rapidly when exposed to the action of the atmosphere, while those with 8-10% or less stand up well. The life of a good sherardized coating depends also upon the thickness of the layer.

The A.S.T.M. Committee A5 has published in its report for 1936 that sherardized, hot dipped, and plated zinc coatings of the same weight have approximately the same service life.

Application—Sherardizing produces a coating of uniform thickness and for this reason can be used on threaded parts like bolts and nuts. The threads are not filled up as is the case with hot dipped nuts or bolts. Allowance can be made for the coating when cutting the threads and after sherardizing they do not have to be rethreaded or tapped.

The principal application is for small steel parts such as bolts, nuts, and washers, or castings which have to resist the action of the atmosphere. Iron wire has also been coated, but the heavy coatings are brittle and crack off when the wire is bent.

Silicon Impregnation

(Siliconizing)

By Harry K. Ihrig*

Introduction—A process of impregnating iron and steel with silicon has been developed.† The silicon-rich case, containing about 14% silicon greatly improves the resistance of the steel to corrosion, heat, and wear.‡ Other methods of producing silicon-rich cases on iron and steel have been studied experimentally,§ but have not resulted in processes of commercial importance.

Metals Treated—Forged, rolled or cast, low carbon steel with low sulphur content is suited for siliconizing. High carbon, low sulphur steels can be treated satisfactorily, but are impregnated more slowly. For example, S.A.E. 1045 steel requires about twice the time for a given depth of case that a low carbon steel requires. The silicon case on high sulphur free machining steels may be penetrated under corrosive conditions, with consequent cracking and spalling of the case due to attack of the underlying core. This attack is probably caused by a less resistant intergranular silicon-sulphide constituent.

White and malleable irons can be treated, but because of their high sulphur content, the resulting cases are, as a rule, not so corrosion or wear resistant as those produced on low sulphur steel. Gray cast irons, because of their high sulphur content and because they grow badly at treating temperatures, do not give a satisfactory case for many purposes.

As a rule, alloy irons and steels, particularly those with a chromium content, do not appear to treat so well as plain low carbon steels.

Preparation of Metals to Be Treated—The decarburized layer often found on forgings does not have to be removed. Sand imbedded in castings must be removed by pickling or sand blasting. Light mill scale does not have to be removed, but heavy annealing scale should be. Because the treatment temperature is above the critical point of irons and steels, it is advisable that all strains be removed before siliconizing; otherwise, they will be removed during the process and may cause distortion.

Silicon Impregnation Process—In the process covered by this article, the iron or steel is subjected to the action of silicon carbide and chlorine at temperatures of 1700-1850°F. Instead of silicon carbide, ferrosilicon or mixtures of ferrosilicon and silicon carbide may be used. Parts may be processed in a rotary or pot type furnace. The chlorine is added when the parts are at temperature. Ordinary carburizing equipment is used with only slight modifications and no inert or reducing gas is necessary during the silicon impregnation.

The exact mechanism of this reaction is not known. At temperatures up to 1850°F. it appears essential that the carbide be in contact with the article to be treated. It is believed that the chlorine liberates the silicon from the silicon carbide in the nascent form, whereupon it diffuses immediately into the article to be treated.

The case may be made any desired depth from 0.005 to 0.100 in. A case of 0.025 to 0.030 in. is usually produced on low carbon steel in two hours. Ordinary cylinder chlorine gas of about 99% purity is used. It is used in the same concentration as in the cylinder. The amount of chlorine gas used depends upon the size of the charge to be treated and the thickness of the case desired. The amount is determined experimentally for a given job and then held constant for the particular charge.

Structure and Composition of the Silicon Case—Fig. 1 is a photomicrograph of a silicon case. The analyses of the 0.010 in. cuts are shown to scale at the side. The silicon content is constant within less than one half of 1% for the first 0.040 in. of the case and then falls off gradually for an additional 0.020 in. or 0.025 in. This uniformity of silicon content in the outer layers makes it possible to grind the silicon impregnated parts to a considerable depth without destroying the best portions of the case.

A peculiarity of the silicon-rich case is that carbon from the outer portions of the article is pushed forward by the silicon and is concentrated underneath the silicon case.

Physical Properties—Siliconized articles show a case hardness of Rockwell B 80-85. Although not file hard, such parts cannot be machined or cut with a hacksaw by ordinary means.

*Director of Laboratories, Globe Steel Tubes Co., Milwaukee, Wis.

‡Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

†Commercially known as Ihrigizing.

Standard tensile test pieces cut from the same bar of S.A.E. 1015 steel show the following results before and after impregnation with silicon:

Untreated	
Elastic Limit, psi	37,750
Ultimate Strength, psi	60,550
Elongation in 2 in., %	38.5
Case cracked at, psi
Treated	
	(.033 in. case)
Elastic Limit, psi	37,900
Ultimate Strength, psi	51,400
Elongation in 2 in., %	19.5
Case cracked at, psi	41,600

The case does not crack until the steel is pulled beyond the elastic limit. After the case cracks, the cross section is reduced and thus the ultimate strength is lowered. The ductility of the case is not so high as that of the core, but treated tubes are ductile enough to be rolled into headers. The case will not spall off under vigorous hammering. However, sharp corners should be rounded off to provide core support for all portions of the case.

The impregnation with silicon destroys all previous heat treatment. The case cannot be changed by any known heat treatment, but the core may be heat treated to give any properties possible with the particular type of base metal used.

Corrosion Resistance—Silicon impregnated articles are re-

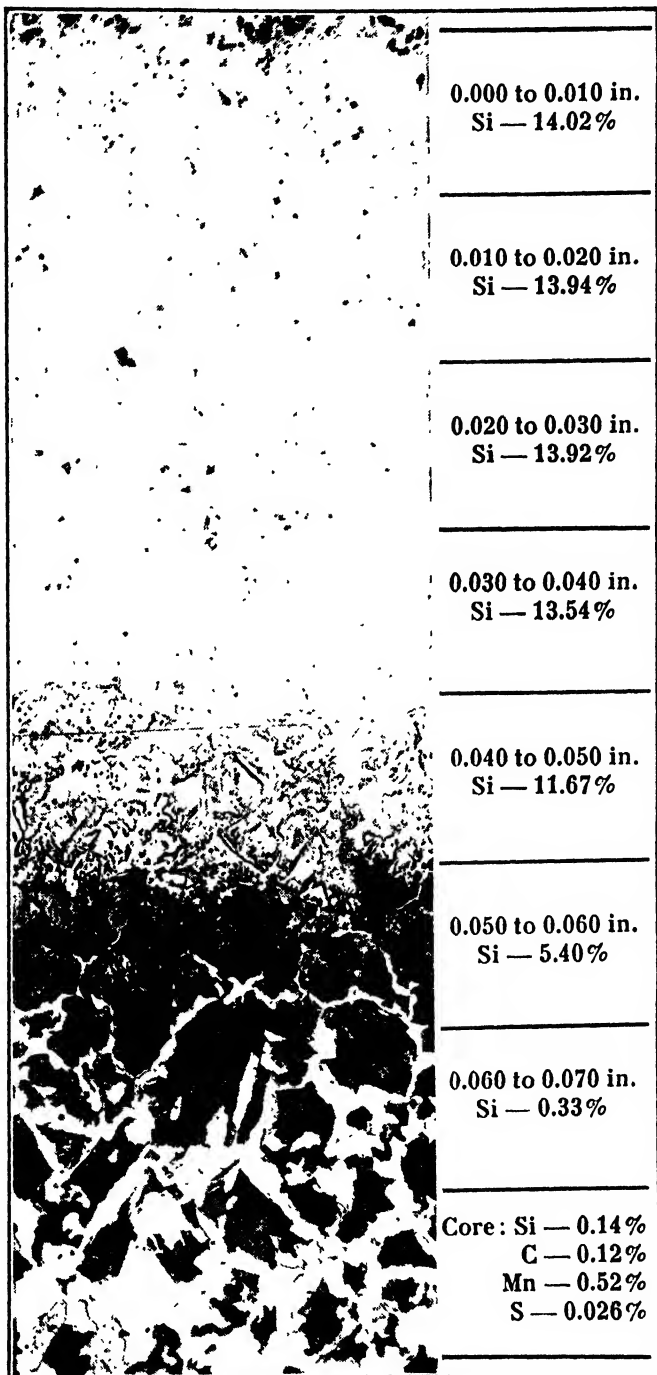

Fig. 1—Photomicrograph (100x) of silicon impregnated case with analyses of 0.010 in. layers.

sistant to nitric, sulphuric, and hydrochloric acids with a decreasing resistance in the order named.

Fig. 2 shows a treated bar which has been cut in two. One half has been boiled in dilute nitric acid until the entire core dissolved leaving only the case. The other half has been etched lightly to show the case.

In 10% boiling sulphuric acid, a $\frac{1}{2} \times 2$ in. round after treatment showed the following losses in weight:

1st 24 hours—3.1% loss	6th 24 hours—0.2% loss
2nd 24 hours—0.5	7th 24 hours—0.7
3rd 24 hours—0.3	8th 24 hours—0.7
4th 24 hours—0.4	9th 24 hours—0.7
5th 24 hours—0.4	10th 24 hours—0.3

Characteristic of high silicon alloys, the attack in the first 24 hours is relatively large, but after that it is greatly decreased. Carbon steel under these same conditions is entirely dissolved in about 18 hr., and 18-8 stainless steel in 24-30 hr.

Silicon-cased articles are not recommended for use in boiling mineral acids, because after the case is perforated the core is rapidly attacked.

The object of silicon impregnation is to produce an article economically that is resistant to corrosion. Because the alloy is only in the surface layers which are exposed to the corrosion, the core or major portion of the piece is of cheaper metal.

Fig. 2—Bar with silicon case; cut in half, one surface lightly etched and the other boiled in dilute nitric acid, leaving only the corrosion resistant shell.

Heat Resistance—The silicon case is resistant to scaling up to 1800°F. At this temperature excessive grain growth occurs in the steel core and the case tends to crack, but at temperatures of 1200-1600°F. long life has been obtained.

Wear Resistance—Under conditions of frictional wear, such as those to which shafts and cylinder liners are subjected, the silicon case has stood up well and the surface is particularly nongalling. Silicon case parts wear well against themselves. Where conditions of corrosion and wear exist together, the silicon case is especially effective.

Table I
Amsler Wear Tests
SAE 1015 Steel

10% Slippage and 1/16 in. Side Motion

Specimens	Rockwell C	Load, kg.	Revolutions	Loss in Dia., in.	Remarks
Carburized vs. Carburized	61	100	200,000	.005	Corners chipped
Sil. Impreg. vs. Sil. Impreg. Not boiled in oil	5	100	200,000	.001	No chipping
Sil. Impreg. vs. Sil. Impreg. Boiled in oil and wiped dry	5	100	1,000,000	.001	No chipping

10% Slippage, 1/16 in. Side Motion, and 1/32 in. Bump

Sil. Impreg. vs. Sil. Impreg. Boiled in oil and wiped dry	5	50	100,000	.000	No chipping
Carburized vs. Carburized	61	50	100,000	.001	Chipping started at 20,000 rev.

If a part, after treatment and finish grinding, is heated to 250-300°F. in a heavy oil, some of this oil is absorbed, and thus the treated part functions as a self lubricated bearing. This oil absorbing property is especially effective where outside lubrication is impossible. Table I gives the results of some Amsler wear tests on silicon impregnated test pieces in comparison to carburized ones. The effect of the oil absorption can plainly be seen.

The reason for the oil absorption is not certain, but it is believed that the case contains graphitic spots or voids left by the graphite that retain the oil.

The silicon case is not recommended for high velocity abrasion, such as found in sand blasting.

Distortion—A slight swell, that can not be adequately explained, occurs during the treatment of steel parts. This varies with the type of metal or alloy treated. Parts actually lose in weight during treatment because the heavier iron has been replaced by the lighter silicon, thus causing an over all loss in weight. The following table illustrates the changes in dimensions and weight on a 1 in. bar made from S.A.E. 1020 steel before and after treating:

	Before Treatment	After Treatment
Weight, g.	602	571.4
Diameter, in.	1.000	1.003
Length, in.	5.985	5.989

Because parts are not quenched after the silicon impregnation, little distortion occurs. Where the type of part permits, it may be straightened cold a few thousandths of an inch, or considerably more if heated to a temperature of about 1200°F.

Applications for Silicon Impregnation—Siliconized parts made from ferrous metals have given satisfactory service when subjected to corrosion, heat, or wear and the following will illustrate some of the applications:

Automotive water pump shafts, rocker arms, cylinder liners, and valve guides; valves, fittings and similar parts for the chemical, paper, and oil industries; forgings, steel, and malleable iron castings, thermocouple tubes, nails, screws, bolts, and tubing are siliconized where corrosion, heat or wear are problems.

Careful testing is essential before starting production to determine if the process is applicable to the particular service required of the part.

Electroplated Metal Coatings

By William Blum*

Scope—The purpose of this section is to summarize those factors in the selection, application and testing of plated coatings that are likely to be of interest to those metallurgists and engineers who are not directly connected with plating operations. When more detailed information is required it can be found in the textbooks and articles referred to.

As practically all of the metals that are applied by electroplating are nonferrous, these processes might be classified under nonferrous metallurgy. Actually, the largest part of commercial plating is applied to iron and steel, though there are extensive applications of plating to copper, brass, nickel-brass, zinc, zinc-base die castings, and aluminum. To avoid duplication, the important commercial plating processes will be summarized in this section, with appropriate references to their applications to either ferrous or nonferrous metals.

The Selection of Electroplated Coatings—The choice of a plated (or other) coating for a specific purpose depends upon the advantages and limitations of that coating. Electroplating has been defined as "the electrodeposition of an adherent coating upon an electrode for the purpose of securing a surface with properties or dimensions different from those of the base metal." Among the specific reasons for applying plated coatings are the following:

1. To produce and retain a desired appearance, for example color and luster. This requirement usually involves also resistance to tarnish. In general (unless lacquer is subsequently applied) this aim can be accomplished by plating with the noble metals, such as platinum and gold, or with less noble, but passive metals, such as nickel and chromium. Silver resists oxidation,* but is readily tarnished by sulphur compounds, and copper is tarnished both by oxygen and sulphur.

2. To protect the base metals against corrosion. Because uncoated iron usually rusts on atmospheric exposure, it is customary to apply some protective coating. Plated metal coatings may protect iron in two ways.

- (a) The coating is less resistant to initial corrosion than iron, and therefore protects small exposed areas of iron by electrolytic action; in which process the coating is anodic, that is, it dissolves; and the base metal is cathodic, that is, is protected against corrosion. The two metals of this class that are applied commercially are zinc and cadmium. Coatings of both of these metals furnish prolonged protection to steel in mild or marine atmospheres, but are rather rapidly attacked in industrial locations, where sulphur compounds are present. Under the latter conditions, zinc lasts longer than cadmium coatings of the same thickness.¹ For either zinc or cadmium the protection is practically proportional to the thickness. Electroplated zinc furnishes about the same protection as zinc coatings of the same thickness that are produced by hot dipping or sherardizing.²

- (b) The coating is more resistant to initial attack than the steel. This is true of copper, nickel, tin, lead, chromium, silver, gold and practically all electrodeposited metals except zinc and cadmium. Such coatings furnish complete protection to the base metal only if they are impervious. If any pores exist, corrosion of the steel at those points is usually accelerated. The most practical method of decreasing the porosity and increasing the protective value, is by increasing the thickness of the coating.³ Of these metals, nickel is most commonly used to protect steel against corrosion. A preliminary coating of copper is frequently applied, partly because the copper may be more cheaply polished than the underlying steel or the superimposed nickel. The customary thin chromium layer increases the resistance to tarnish, but adds little to the protection against corrosion. Tin and silver coatings are used largely because of their resistance to foods and beverages. Lead is generally applied for resistance to sulphuric acid.

All plated metals applied commercially to zinc or aluminum are more noble than these base metals, and must therefore be thick enough to be nearly impervious in order to furnish good protection against corrosion. As a first approximation, about the same thickness of nickel, or of copper plus nickel, is required on zinc or aluminum as upon steel. On copper and brass, thinner coatings of nickel are usually adequate.

The electrochemical series of equilibrium potential is a rough guide to the

*Chemist, National Bureau of Standards, Washington, D. C. Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

ability of a metal coating to protect other metals against corrosion, but there are many practical exceptions. Although the standard potential of cadmium is less negative (more noble) than that of iron, a cadmium coating protects iron that is exposed through small pores. On the other hand, under equilibrium conditions, chromium is more negative (less noble) than iron, but, because chromium becomes passive in the air, it accelerates the corrosion of exposed iron.

3. To protect a base metal against some specified chemical reaction. The most extensive use of this type is that of copper plating to prevent certain parts of steel articles from absorbing carbon during case hardening. Experience indicates that the thickness of copper coating determines the protection afforded for any given period and temperature of hardening.⁴ It is probable that the increased thickness is effective by reducing the porosity.

A similar application, usually confined to laboratory practice, is the use of silver coatings to protect steel against oxidation during heat treatment. Chromium is helpful, but not apparently equal to silver for this purpose. Nickel plated steel is used in alkaline storage batteries and oxygen-hydrogen cells, because nickel resists alkaline solutions. Nickel and chromium coatings are used in the manufacture of films and plastics, because these metals resist most organic compounds.

4. To protect the base metal against wear, caused by either abrasion or erosion. (Erosion is here defined in the same sense as "surrosion," that is, the combined result of corrosion and abrasion.) Resistance to abrasion requires that the coating shall be harder and "tougher" than the base metal. Protection against erosion involves also ability to resist chemical attack by the surrounding medium. Chromium more nearly meets these requirements than any other single plated metal, and is extensively used for wear resistance on gages, dies, molds, printing plates, and certain cutting tools. (See the article on "Hard Chromium Plating" in this Handbook.)

5. To increase the dimensions. This process, known as "building up," may be applied to parts accidentally made undersize, or to worn parts. Coatings to serve this purpose must be at least as hard as the metal to which they are applied. The three metals commonly used are iron, nickel, and chromium. Iron has the advantage of cheapness (significant in large scale operations) and the fact that it can be subsequently case-hardened. Nickel is the most easily applied, and its hardness can be controlled over fairly wide limits. Chromium is most commonly used when greater wear resistance is desired than can be secured with the base metal alone. Two practical difficulties that have limited the use of building up (especially in America with high priced labor) are the selection and application of suitable "stop-offs" to prevent deposition on areas not to be built up, and the care needed to consistently secure the high degree of adhesion usually required.

The Specification and Testing of Plated Coatings—The principal properties of coatings that determine their value, and may therefore serve as a basis for specifications are (1) thickness, either average or minimum, (2) porosity, (3) adherence, (4) hardness, and (5) luster.

A—Methods of Test—(1) *Thickness*—The average thickness is estimated by stripping (dissolving) the coating from a known or measured area, and determining its amount by loss in weight or by chemical analysis of the resultant solution. The average thickness has been the basis of most plating specifications, but now is being replaced by requirements for a certain minimum thickness on significant surfaces.

The minimum thickness, or the thickness of coating at any point may be measured by: (a) Microscopic examination of a suitable cross section.⁵ (b) The "chord" method,⁶ in which the coating is cut through with a grinding wheel of known radius. (c) Methods depending upon rate of chemical reaction, such as the Preece test for zinc coatings,⁷ the "spot" test with concentrated HCl for chromium coatings,⁸ the "dropping test" for zinc and cadmium deposits,⁹ and the "jet" test for nickel coatings.⁹ (d) Nondestructive magnetic methods, which depend either upon the attraction of a magnet to the coating¹⁰ (for example to nickel on a non-ferrous base metal); or upon the reduction in attraction of the magnet by the presence of a nonmagnetic coating¹¹ such as copper, zinc, or chromium on a magnetic base metal such as iron or steel. Of these methods, the microscopic is the most reliable (except for very thin coatings) and is usually the basis of umpire tests.

The minimum thickness obtained on a given article depends upon, and can be controlled by, the average thickness, that is, the time and current density used; and the distribution of coating. The latter depends upon the throwing power of

the solution and upon the shape of the article and its position with respect to anodes and racks.

(1) *Porosity*—Small pores in zinc and cadmium coatings that are more than 0.0002 in. thick have little significance. Porosity of more noble coatings on steel may be detected and roughly estimated by some form of ferroxy test such as the ferroxy paper,¹³ and by the boiling water test,¹³ but the results are not sufficiently quantitative to be used in specifications. With the noble coatings, the salt spray test is principally a measure of porosity.

(2) *Adherence*—Poor adherence can be detected by deforming the specimen, for example by bending, twisting, hammering, extruding, or stretching. These methods do not yield quantitative results. The methods of Ollard¹⁴ and Jacquet¹⁵ for measuring adhesion require special specimens and are not applicable to finished products.

(3) *Hardness*—Most of the customary methods of measuring hardness are directly applicable to plated coatings only when the latter are much thicker than those used commercially, because with thin coatings, the results are influenced by the base metal. The results on thick coatings do not necessarily represent the properties of the thinner coatings usually applied in commercial plating. Measurements show that for each plated metal, it is possible to vary and control the hardness over a fairly wide range by altering the conditions of deposition. For example, electrodeposited nickel and iron vary in Brinell hardness number from about 150 to 400; and chromium from about 500 to 900. No simple correlation has been found between the results with each hardness test and the behavior in service.¹⁶ In those cases, such as intaglio printing plates, in which wear is caused principally by abrasion, the scratch hardness is at least roughly proportional to the wear resistance.

(4) *Luster and Reflecting Power*—Egeberg and Promisel¹⁷ express the brightness of a plane surface as the ratio of the specular reflection (in which the angle of reflection is equal to the angle of incidence, 45° in their tests) to the diffuse reflection (that is, the reflection at all other angles). This method is applicable only to plane specimens, but may be useful in research, especially upon deposits from "bright plating" solutions.

(5) *Protection Furnished Against Corrosion*—Continuous exposure in typical atmospheres¹⁸ yields results that are closely related to the life in similar service, but such tests require months or years. Accelerated corrosion tests are useful for comparing the behavior of similar coatings under conditions corresponding to those in the test.¹⁹ For example, the salt spray test yields results that may be similar to those in marine, but not in industrial locations.

B—Typical Specifications—Tentative specifications adopted by the American Electroplaters' Society and the American Society for Testing Materials²⁰ may be summarized as follows:

Nickel and Chromium Coatings on Steel.

	Type KS General Service	Type QS Mild Service
	Minimum thickness on significant surfaces,	
	Inches	Inches
Copper plus nickel.....	0.00075	0.0004
Final nickel	0.0004	0.0002
Average thickness* chromium (if required).....	0.00002	0.00002
Salt spray, continuous exposure.....	48 hr.	16 hr.

*It has been recently suggested that this requirement might be replaced by a minimum thickness of 0.00001 in. chromium, measured by the spot test with concentrated HCl.

Zinc or Cadmium Coatings on Steel.

Type LS—Zinc NS—Cadmium General Service	Type RS—Zinc TS—Cadmium Mild Service
Minimum thickness on significant surfaces,	
Inches	Inches
0.0005	0.00015

Important Factors in Electroplating—The quality, including appearance, adhesion, porosity and protective value of electroplated coatings, depends upon numerous factors such as:

Base Metal—It is not possible to apply high quality coatings to poor quality metals. The composition of the base metal should be known and controlled. The structure of the base metal may affect the reactions in cleaning and pickling processes, and the structure of the coating. The condition of the surface, including the degree and nature of the polishing processes, and the presence of pores, cracks, or inclusions, has a direct bearing upon the character and porosity of the coatings.

Preparation for Plating—It is necessary to have a chemically clean surface upon the base metal to secure good adhesion of deposits. The preparation usually involves "cleaning," that is, removal of grease and foreign particles; and "pickling" (for steel) or "dipping" (for nonferrous metals) to remove oxides or other compounds (including absorbed alkali), and in some cases to etch the surface. Methods of cleaning are described on page 1123, and of pickling on page 1131. In some cases surfaces are prepared for plating by sand blasting (page 1142) or rolling (page 1144).

Electrodeposition—In the actual plating process, it is desirable to control by appropriate measurements and tests:

a. The composition of the baths, including the concentrations of major constituents and of objectionable impurities. In general, it is not necessary to keep the major constituents more nearly constant than $\pm 5\%$ of the amounts present, and analytical methods that are accurate to $\pm 2\%$ are usually adequate. The permissible content of each impurity must be determined by experience under the conditions employed. The acidity or pH should be controlled in all except very strongly acid or alkaline solutions.

b. The temperature of the bath should be kept within specified limits, which are narrower for chromium than for other plating baths.

c. The average current density must be kept within desired limits, for the sake of uniformity in thickness and quality of coatings.

d. In many baths agitation permits an increase in the current density. Some agitation is secured by the movement of oscillating rods or continuous conveyors, but stronger agitation is sometimes obtained with air or with rotating electrodes.

e. In general, the anodes should be of such composition and structure as to maintain the metal concentration and the pH, that is the anode efficiency should be nearly the same as the cathode efficiency. In chromium plating and a few other operations where insoluble anodes are used, the metal content is maintained by replenishment.

Equipment—(a) *Electrical*—Practically all commercial plating is conducted with motor generator sets, usually with potentials from 6-12 volts, and with currents depending upon the area of work to be plated and the current density. In recent years, large copper oxide rectifiers have been used abroad for plating.

(b) *Tanks*—The tanks are usually constructed of (a) wood, used principally for rinse tanks; (b) steel, used for alkaline cleaning and for cyanide plating baths; (c) rubber lined steel, used for acid pickles, acid copper baths, and nickel baths; (d) lead lined steel or wood, used for sulphuric acid pickles, acid copper baths and chromium plating; and (e) acid proof stoneware, used for dips containing nitric acid and for small plating baths.

Typical Plating Baths and Conditions—The following concentrations and conditions are typical, but they may require changes to meet specific needs.

Copper Plating

(a) Acid bath, used in electrotyping, and for intermediate layers of copper, or for copper on brass.

Copper sulphate, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, oz. per gal.....	27
Sulphuric acid, H_2SO_4 , oz. per gal.....	8
Temperature, °F.	75-120
Current density, amp. per sq.ft.....	20-40

(b) Cyanide bath, used for plating copper directly on steel, as well as on brass or zinc.

Copper (cuprous) cyanide, CuCN , oz. per gal.....	3
Sodium cyanide, NaCN , oz. per gal.....	4.5
Sodium carbonate, Na_2CO_3 , oz. per gal.....	2
(Free sodium cyanide), NaCN , oz. per gal.....	1
Temperature, °F.	95-120
Current density, amp. per sq.ft.....	3-15

(c) Rochelle salt, cyanide bath, used especially for plating copper on zinc-base die castings.

Copper cyanide, CuCN , oz. per gal.....	6
Total sodium cyanide, NaCN , oz. per gal.....	7.5
Free cyanide, NaCN , oz. per gal.....	0.75
Rochelle salt, $\text{NaKC}_4\text{H}_4\text{O}_6 \cdot 5\text{H}_2\text{O}$, oz. per gal.....	6
Sodium carbonate, Na_2CO_3 , oz. per gal.....	4
Temperature, °F.	130
Current density, amp. per sq.ft.....	30-40

Nickel Plating

(a) Plating on steel or brass at low current density.

Nickel sulphate, $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, oz. per gal.....	16
Ammonium chloride, NH_4Cl , oz. per gal.....	2
Boric acid, H_3BO_3 , oz. per gal.....	2
pH	5.3
Temperature, °F.	70-90
Current density, amp. per sq.ft.....	10-20

(b) Plating on steel or brass, and over copper on zinc at high current densities.

Nickel sulphate, $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, oz. per gal.....	30-40
Nickel chloride, $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, oz. per gal.....	6
Boric acid, H_3BO_3 , oz. per gal.....	4
pH, high	5-5.2
low	2-5.5
Temperature, °F.	100-150
Current density, amp. per sq.ft.....	20-50

(c) Plating directly on zinc die-castings.

"High Sulphate Bath"

Nickel sulphate, $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, oz. per gal.....	10
Sodium sulphate, Na_2SO_4 , oz. per gal.....	15
Ammonium chloride, NH_4Cl , oz. per gal.....	2
Boric acid, H_3BO_3 , oz. per gal.....	2
pH	5.5
Temperature, °F.	70-80
Current density, amp. per sq.ft.....	20-30

Chromium Plating (See also p. 1102)

Chromic acid, CrO_3 , oz. per gal.....	30-50
Sulphuric acid, H_2SO_4 , oz. per gal.....	0.3-0.5
(The sulphuric acid, or an equivalent amount of any soluble sulphate, should be in such concentration that the ratio $\text{CrO}_3/\text{SO}_4 =$ about 100.)	
Temperature, °F.	100-160
Current density, amp. per sq.ft.....	60-500

The temperature and current density should be so related as to give a cathode efficiency of about 12% for bright deposits and 16% for hard deposits. In general, the current density must be increased as the temperature is raised, and be slightly higher for hard deposits than for ornamental coatings. For example, at 113°F., current densities from 100-150 amp. per sq.ft. yield bright deposits, and from 150-200 amp. per sq.ft. yield slightly dull but harder coatings.

Zinc Plating

(a) Acid Bath.

Zinc sulphate, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, oz. per gal.....	50
Aluminum chloride, $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$, oz. per gal.....	3
Sodium sulphate, Na_2SO_4 , oz. per gal.....	10
pH	3-4
(Organic addition agents are frequently used to produce brighter deposits).	
Temperature, °F.	70-95
Current density, amp. per sq.ft.....	20-50

(b) Cyanide Bath.

Zinc cyanide, $\text{Zn}(\text{CN})_2$, oz. per gal.....	8
Sodium cyanide, NaCN , oz. per gal.....	3
Sodium hydroxide, NaOH , oz. per gal.....	7
(Various addition agents, both organic and inorganic, are often used to produce brighter deposits).	
Temperature, °F.	70-95
Current density, amp. per sq.ft.....	10-30

Cadmium Plating

Cadmium oxide, CdO , oz. per gal.....	6
Sodium cyanide, NaCN , oz. per gal.....	16
(With organic and inorganic addition agents as brighteners).	
Temperature, °F.	70-95
Current density, amp. per sq.ft.....	10-30

Tin Plating

Sodium stannate, Na_2SnO_3 , oz. per gal.....	12
Sodium hydroxide, NaOH , oz. per gal.....	1
Sodium acetate, $\text{NaC}_2\text{H}_3\text{O}_2$, oz. per gal.....	2
Hydrogen peroxide, H_2O_2 (25 vol.), oz. per gal.....	0.3
Temperature, °F.	130-160
Current density, amp. per sq.ft.....	20-60

Lead Plating

Basic lead carbonate, $\text{Pb(OH)}_2 \cdot 2\text{PbCO}_3$, oz. per gal.....	20
Hydrofluoric acid, HF (50%), oz. per gal.....	32
Boric acid, H_3BO_3 , oz. per gal.....	14
Glue, oz. per gal.....	0.03
Temperature, °F.....	70-90
Current density, amp. per sq.ft.....	10-20

Iron Plating

Ferrous chloride, $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$, oz. per gal.....	40
Calcium chloride, CaCl_2 , oz. per gal.....	45
Temperature, °F.....	190
Current density, amp. per sq.ft.....	50

Brass Plating

Copper cyanide, CuCN , oz. per gal.....	3.6
Zinc cyanide, Zn(CN)_2 , oz. per gal.....	1.2
Sodium cyanide, NaCN , oz. per gal.....	7.5
Sodium carbonate, Na_2CO_3 , oz. per gal.....	4.0
Temperature, °F.....	90-120
Current density, amp. per sq.ft.....	2-5

Silver Plating

Silver cyanide, AgCN , oz. (troy) per gal.....	4.4
Potassium cyanide, KCN , oz. (avoir.), per gal.....	5.0
Potassium carbonate, K_2CO_3 , oz. (avoir.), per gal.....	5.0
Temperature, °F.....	70-90
Current density, amp. per sq.ft.....	2-10

Before plating silver on most base metals, it is usually necessary to plate them for a few seconds at a high current density in a more dilute silver cyanide bath known as a 'strike' solution.

Industrial or "Hard" Chromium Plating

By D. A. Nemser* and W. E. Bancroft†

Definition—The chromium in "hard" chromium plating, as distinguished from decorative chromium plating is usually deposited in appreciable thicknesses directly on the base metal. This type of plate is finding wide industrial application. Ordinarily, the base is fully or semihardened steel. In some cases, however, successful applications have been made on soft steel, cast iron, and many nonferrous alloys. Fairly heavy deposits must be made on the softer base materials if heavy pressures are encountered in service.

The plate depth usually is in the range of 0.0001-0.040 in. or more. The heavier deposits are used chiefly for salvage purposes.

Hardness—The outstanding property of electrochemically deposited chromium is its resistance to wear. Schneidewind reports that the average deposit will show the following hardness values: Vickers-Brinell 625, Mohs 8, and scratch width with Bierbaum Microcharacter test of 2 microns. In employing these values, however, it must be borne in mind that the plating conditions have a profound effect on the hardness of plate. These figures must therefore be regarded as approximate.

Chromium plate manifests a file hard reaction to a temper testing file. Wear resistance far superior to that found with fully hardened tool or die steels is obtained.

Toughness—The plate is extremely brittle and should not be employed for tools subjected to shock. The toughness can be somewhat increased without depreciating wear resistance by heating to temperatures under 500°F. This treatment will rid the plate and steel base of occluded hydrogen. A temperature of 300-400°F. is ordinarily employed.

In this connection, it is well to consider that the deposited plate is really a solid solution "alloy" of chromium and hydrogen. Schneidewind has shown that the hardness remains constant until a somewhat critical range at 525-550°F. is reached. Beyond this, a marked falling off in hardness occurs, indicating the decomposition of the "alloy". The hardness decreases gradually at higher temperatures. At 1900°F. the plate will show a Mohs hardness of 4.5 and a Vickers-Brinell of 150. It is then considered fully annealed, manifesting properties similar to cast chromium, as it is soft, ductile, and malleable, and possessing extremely poor wear resistance.

Coefficient of Friction—The low coefficient of friction of chromium plate is also advantageous. It minimizes friction in metal to metal contact. The plate is characterized as being "slippery, greasy, and nonwetting".

Chemical Resistivity—Chromium plate is not affected by most organic chemicals, alkalies, sulphur, and sulphur compounds. Nitric acid will not dissolve it. The plate is readily attacked by hydrochloric acid and slowly by sulphuric acid.

Corrosion Resistance—Chromium plate does not tarnish or corrode in ordinary atmospheres. However, fairly thin deposits are apt to contain cracks and pinholes which permit corrosive elements to come in contact with the base metal. Proper control of plating conditions minimizes this tendency.

Melting Point—Chromium melts at 2822°F. and retains a bright surface up to approximately 900°F., therefore, serving well for some high temperature applications. Its coefficient of expansion, however, is less than that of most metals, and therefore, flaking of plate might occur, where the plated object is subjected to wide temperature changes.

Miscellaneous Properties—Chromium is nonmagnetic, which opens a field in rendering nonferrous electrical parts longer wearing. It prevents the sticking of resinous plastics, rubber, paper, and celluloid to forming molds. Chromium has approximately the same heat and electrical conductivity as aluminum, and approximately half that of copper and silver. Another feature favoring the use of chromium plate is its adaptability. It can be applied on the standard product with a minimum departure from established manufacturing routine. Chromium

plate possesses a bright pleasing appearance, which aids materially in the marketing of the product.

Plating Method—It is not within the scope of this writing to give a detailed account of all the many factors which enter into the deposition of hard chromium plate. However, an attempt has been made to give a general outline of practices employed in plating the ordinary run of work.

Cleaning—Before plating, the work surface should be rendered chemically clean. Dirt, grease, and oil should be removed either with organic solvents or alkaline metal cleaner. The various manufacturers of these materials are thoroughly equipped to analyze any cleaning problem and supply the proper type of material. Scale, rust, oxide, and tarnish are removed by pickling or dipping in acid solutions. The most commonly used are hydrochloric and sulphuric acids. These may be used singly or combined, in varying concentrations and at varying temperatures, depending on the type and quantity of foreign matter to be removed. Sometimes electrolytic acid pickling is the only satisfactory way to remove heavy scale, especially on deeply recessed parts.

Sandblasting, hand scrubbing, polishing with emery cloth and buffing are useful adjuncts to the cleaning operation. Sandblasting, of course, roughens the surface but where the work is to be ground or polished after plating, this is not a disadvantage. In fact, on some types of alloy steels, sandblasting has been found imperative in producing a sound, tightly adhering plate. Buffing may be used to remove light rust, tarnish, and fingerprints. This operation leaves a film of grease which protects against further rusting while being racked up. It is easily removed in the cleaner. The authors realize that there might be some objection to the practice of buffing due to the smooth surface formed. However, their own practical experience indicates that buffing may be advantageously employed for certain cases.

Racking—Work to be chromium plated is usually racked in one of the following ways:

1. Parts which require only a comparatively thin plate (usually 0.0002-0.0003 in.) over the entire surface may be mounted on frame-like racks equipped with phosphor bronze spring wires, battery clips, bolts, or some other similar device, to hold work tightly. These racks are hung on the cathode bar between rows of flat lead anodes.

2. Parts requiring several thousandths of plate evenly distributed, as, for example, plug gages and shafts, may be assembled in connection with anodes made of sheet lead formed into shape conforming to that of the work and located a set distance from surface to be plated. Holes, such as ring gages and dies, may be plated by placing anodes made of lead wire or tubing in the center of hole.

3. In some cases, good results are obtained by placing a flat or curved lead anode before a straight cylindrical piece of work and rotating the latter while plating.

Parts, unless heavy, must not be hung on hooks or held loosely in the bath. Positive, tight contact must be maintained.

Conforming anodes should be mechanically connected to the work-holding fixture to insure uniform spacing but, of course, insulated from it electrically. Work should be held in such position that gas pockets are not formed and that drag out is not excessive. Racks may be insulated by coating with special "stop off" lacquer or wrapping with rubber tape and then lacquering.

When it is desired to keep certain sections of the work free from plate, this may be accomplished by wrapping with sheet lead or lead foil, lacquering, wrapping with tape or sometimes covering with sleeves or plates made of steel, copper, glass, or porcelain, depending on whether insulating or conducting properties are desired. If the work must remain in the plating tank for appreciable time intervals, the tape should be covered with lacquer to prevent its disintegration.

Plating—After work has been properly cleaned, pickled, and mounted in racks, it is given the following or some similar treatment:

1. Two to three minutes in metal cleaner to remove dirt, oil, buffing compound, or fingerprints. Use direct current, 6-8 volts, and operate at about 200°F. with work as cathode. When using frame racks containing work only, the iron tank lining may be used as anode although separate steel plates hung alongside the tank are recommended. When using composite assembly containing conforming anodes, these anodes are connected into the circuit on positive side.

2. Cold water rinse.

3. One half to two minutes with reverse current in a solution of sulphuric acid of 50° Baumé at about 6 volts. This slightly etches the surface of work and provides better adherence.

Note—A solution of warm chromic acid (20° Baumé) with reverse polarity at about 6 volts may be used here. In this instance no subsequent rinse is necessary and the work may go directly into the plating bath.

4. Cold water rinse, if sulphuric acid etch is used.

5. Immerse in plating bath at low current and build up to plating current slowly, taking about 5 min. Plate under carefully selected current density and temperature conditions the length of time required to get desired thickness of deposit.

6. After plating, rinse in clean, cold water, then hot water and finally dry, using air blast or hardwood sawdust. If more convenient, work may be unracked and rinsed before drying.

Plating Solution—The plating solution may be made according to one of the following formulae:

Chromic acid	250 g. per l.	Chromic acid.....	400 g. per l
Sulphuric acid.....	2.5 g. per l.	Sulphuric acid.....	4.0 g per l
Baumé	21°	Baumé	31°

Other compounds containing the SO_4 radical may be used in place of sulphuric acid, the important point being that the ratio between chromic acid and sulphate radical be fixed and controlled within narrow limits. Variations in ratio usually necessitate changes in some of the other factors.

The plating solutions are best operated warm, somewhere between 100 and 150°F.; 120°F. is a satisfactory temperature. A uniform temperature must be maintained. In general, the higher temperatures necessitate higher current densities to produce equivalent results. It is important for good results to co-ordinate composition of solution with temperature and current density.

Current Density—Amperes per unit of area on work surface is the most important factor in determining plating speed. Too low a current density tends to give a milky deposit. The correct current density yields a bright plate while one which is too high gives a frosty or burnt deposit. A bright plate offers the most satisfactory all-around service. A synchronous motor generator set is desirable to supply the plating current.

Stripping—It often becomes necessary to strip off chromium plate. The most common method of handling this is to immerse the plated object in a cold solution of equal parts by volume of hydrochloric acid and water. This is suitable for any base metal which is not readily attacked by hydrochloric acid. Steel and cast iron are etched but little in this solution if the work is removed as soon as the chromium is entirely dissolved.

Stripping can also be accomplished by employing a sodium carbonate solution, 6-8 oz. per gal., with reverse current and steel cathodes. This solution is extremely desirable for steel and cast iron.

A warm chromic acid solution at 18° Baumé with reverse current is also employed.

Cold sulphuric acid made up of 1 part of water and 3 parts of sulphuric acid with reverse current is particularly good in stripping chromium from zinc and aluminum bearing base metals.

Health Hazard—The voluminous evolution of hydrogen and oxygen during plating mechanically carries a fine spray of plating solution into the air around the plating tanks. The chromic acid contained in this spray may cause severe irritation of the mucous membranes of the nose and throat if inhaled. In order to prevent this hazard, it is advisable to provide adequate exhaust on the plating tanks. A lateral forced draft exhaust system is preferred.

Skin lesions in contact with chromic acid tend to form painful and slow healing chromium ulcers. It is imperative, therefore, to properly protect cuts. A 5% solution of sodium bisulphite or similar reducing agent should be available for neutralizing chromic acid on the hands and arms.

Applications—Gages, tools, and machine parts are plated to increase their surface hardness and give longer life. Cylindrical plug gages, with a residual plate of 0.0015-0.002 in. after finishing to size, often give five times or more the wear obtained with the best grade of hardened tool steel unplated. Taps, reamers, milling

cutters, metal slitting saws, and drills when used on bakelite, hard rubber, bronze, aluminum, fibre, asbestos, copper, cast iron, steel of various composition, wood, and other materials give greatly increased wear life and operate easier when plated.

As a "putting on tool" and salvaging medium in the machine shop chromium plate has no equal. Shafts, arbors, quills or spindles, accidentally machined or worn undersize, may be quickly, easily and effectively brought back to normal. Likewise, holes in gears, cutters, bushings, or dies may be reduced in diameter by almost any amount. On expensive parts salvaging with chromium plate usually represents only a small fraction of the replacement cost and is much quicker.

Mechanics' tools and other items of hardware such as micrometers, calipers, scales, drills, saws, feeler gages, chisels, and scrapers, which are not subjected to outdoor exposure, are greatly improved by a coating of chromium (0.0002-0.0003 in.) directly on the steel base.

Drawing dies and mandrels when chromium plated give 3-5 times the life of bare dies and mandrels in drawing copper, steel, nickel, gold, silver, platinum, and their alloys.

Molds for the various plastic materials, porcelain, glass, and rubber, are greatly benefited by a deposit of chromium. The bright finish is preserved much longer and the plastic material does not stick to the mold, while pitting is reduced or entirely eliminated. The mold wear is reduced and in general the molded product has a better appearance.

Rolls for sheet brass, copper, rubber, celluloid, and paper are being chromium plated quite extensively. The advantage is longer life and increased efficiency due to elimination of sticking and tearing.

Printing and engraving dies are another good subject for chromium deposits, a hard, nondistorted surface being obtained on soft bases such as copper or iron.

Tinning of Steel

By Bruce W. Gonser*

Ferrous materials are usually tinned by hot dipping or immersing the product to be coated in a molten tin bath. Although not so extensively used, other methods are sometimes used as electrodeposition, metal spraying, or fusing a tin powder coating over the material.

In the tinning of ferrous products during recent years 91% of the tin consumed has gone into the production of hot tinned low carbon steel sheet, 3½% for tinned wire, and 4½% for the tinning of cast iron and miscellaneous parts.

The Manufacture of Hot Dipped Tin Plate—The importance of the United States tin plate industry is indicated by the 1937 production of 2,418,190 long tons. Over the last five years it has consumed an average of 22% of the world's production of tin.

The regular grade of thinly coated tin plate is known as coke plate. The composition of the steel used varies, but may contain from 0.05-0.10% C, 0.20-0.45% Mn, about 0.08% P for pack rolling or less than 0.015% for cold rolling, practically no silicon in rimming steel, and from about 0.03-0.05% sulphur. Various single impurities or combinations in the steel used for tin plate may have a marked effect on inhibiting or promoting corrosion in containers used for food. There is no universal specification for sheet for tin plate, since the composition and degree of cold work after annealing must be varied to meet specific uses. Thus, for some food containers the copper content may be limited to below 0.10%, and sometimes a limit is placed on P and Si.

For details on the manufacture of hot and cold rolled strip and sheet, see page 818.

Preparation of Sheet for Tinning—In preparation for tinning both cold reduced and pack rolled sheets are given a "white" pickling in a 3-6% sulphuric acid solution at about 160°F. After washing, the sheets are transferred to portable boshes or tanks containing water slightly acidulated with hydrochloric acid where they are kept wet, ready for tinning. Strip or sheets that have been bright normalized in controlled atmosphere may be placed directly in the boshes for immediate tinning. The base material is always introduced into the tin pot while wet.

Fig. 1—Simplified diagram of pot for making tin plate.

Tinning—With the exception of a small amount of exceptionally heavily coated plate, tin plate is made in automatic tinning machines. These machines feed the base plate through a flux of zinc chloride into a tin bath and up through a palm oil compartment where excess tin is removed (Fig. 1). Auxiliary equipment carries the sheet through proper cleaning attachments where part or practically all of the adhering palm oil is removed and the plate is polished. The pot and rolls of the tinning machine accommodate 2 or 3 sheets to be tinned side by side at the same time. The tin bath of 5-7 tons of first quality tin is usually heated near the entrance end by immersion gas heaters.

Base plate for tinning is automatically fed into the first rolls of the tinning machine by auxiliary equipment which carry a sheet at a time from a storage tank at the front of the pot to an arrangement of rolls in the tin pot. Several sets of conveying rolls and directing baffles force the plate through the flux, the molten tin, under a dividing partition, and into the palm oil compartment. The rolls in the palm oil remove excess tin as they convey the sheet out of the tin pot. The rolls in the tin and palm oil baths are coated with tin, and those in the palm oil are equipped with fixed scrapers of asbestos or soapstone. These aid in removing tin and tin-iron "scruff" which adhere to the rolls from contact with the tin plate. The palm oil rolls are held against the sheets by slight spring pressure.

Palm oil acts as a flux to aid in obtaining good distribution of tin and serves as

*Metallurgist, Battelle Memorial Institute, Columbus, Ohio.

Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

a cooling and protective medium so that the emerging tin quickly freezes without oxidizing. The temperature of the palm oil bath is kept as low as possible (by recirculating) preferably 460-470°F. at the top of the bath. At higher temperatures the palm oil readily polymerizes, which may cause yellow streaks in the tin plate. Sumatra palm oil is generally considered to be the best as it is of more uniform quality and contains a maximum of 5 or 6% oleic acid compared to perhaps double this amount for the African product. The two grades are sometimes mixed. In starting a tin pot some used oil is always mixed with new oil, usually in a ratio of 2 parts used to 1 part new. The average tin pot carries about 1000 lb. of palm oil in the exit compartment.

Steel sheets are passed through the tin pot at the rate of 25-30 f.p.m. The temperature of the bath is governed by the speed of tinning. This may vary from about 575-650°F. at the entrance end of the bath and be 100°F. lower near the palm oil compartment. Some tin is lost as dross and in concentrations of tin along the edges, particularly at the bottom or "list" edge of each sheet, hence the yield as calculated from the tin on the finished sheets near the center is only 85-90% of the tin consumed. Thus an average coating of 1.35 lb. per base box of tin as measured by the consumer may mean a calculated coating of 1.52 lb. based on the tin consumed in the mill.

Removal of palm oil from a finished plate may be effected by absorption in a dry material such as bran or by the use of an alkali cleaner or a combination of the two. Dry flannel rolls may be used for final cleaning. Practically complete oil removal is desired when the plate is to be lithographed or enameled but in other cases a residual film of oil may be desirable to preserve the finish or act as a lubricant in stamping operations.

Classification of Tinned Sheet—Sheets are inspected for finish and classified into various weights. Sheets having no visible defects are termed "primes", those with slight flaws are termed "seconds". "Menders" have more severe defects but are in general salvaged by straightening, cutting away damaged portions, or re-tinning. Waste sheets having prohibitive defects, such as badly crumpled sheets, are sent with scrap to be detinned. The proportion of prime sheets produced varies widely from time to time but in general will average about 85% of the total, with roughly 10% of the production going to seconds and for retinning, and 5% to waste.

Tin plate is measured and sold by the base box as defined in Table I, which also gives a tabulation of some of the weights and thicknesses of common tin plate. The tolerance on specified dimensions is usually $\frac{1}{8}$ in. Standard coke plate in the United States carries about 1.35 lb. of tin per base box or a coating of tin about 0.00007 of an in. in thickness. Better grades carry 1.50 and up to 1.75 lb. per base box.

Testing Tin Plate—Since practically all hot dipped tin plate is used in can making or closures for cans and bottles, its resistance to corrosion is an important property and is frequently tested at the tin mill as well as by the fabricator. The best test method is by actual performance records. Accelerated tests are made by maintaining the packed container at an elevated temperature. An even more accelerated test being rather widely used is to measure the time for a definite amount of hydrogen to be evolved when the tin plate is submitted to the action of warm dilute hydrochloric acid under standardized conditions.

Charcoal Plate—Heavier coatings of tin than those normally used in can making are designated as charcoal plate, a term originating in the superior quality of base plate once made by means of charcoal reduction.

Charcoal plate is tinned by machine in the same general manner as previously described, but with wiping rolls so adjusted that the tin coating left is relatively great, as 2-4 lb. per base box. For similar or for heavier coatings, hand dipping or a combination of hand and machine operation is used. More tin is made to adhere by dipping in molten tin kept at a relatively low temperature, then dipping in palm oil. Sometimes heavy coatings are produced by redipping at least once in another tin bath of higher purity. In this way coatings up to about 7 lb. per base box are obtained and even heavier coatings can be made.

Terne Plate—The steel sheet base forterne plate is prepared in the same way as in making tin plate. Much of the thinly coated terne plate is made in the same way and with the same machinery as is used in making tin plate. The only difference is that a terne metal bath contains an alloy of tin and lead, and the temperature of the bath is somewhat higher, also, a flux of zinc ammonium chloride is sometimes used in place of zinc chloride. Terne plate, such as that used in making

*Most used.

Weights of 55-65 lb. per base box are often designated as taggers' tin. Plate most used by can makers is covered by the weight range between 80 and 135 lb. per base box.

lubricating oil containers, contains from 18-25% tin. The coating for such cans is very thin, amounting to 1.15-1.25 lb. per base box which is only 70% the thickness of similar weights of tin plate.

Common "roofing tin" is heavily coated, hand dipped, terne plate which is usually designated as "short terne" to differentiate from the "long terne" or larger sheets. The composition of the base plate is usually selected with some regard to atmospheric corrosion resistance and is frequently machine coated with the terne mixture as part of the preparation for hand dipping. For roofing, a 25% tin-75% lead bath is commonly used. Sheets are dipped singly in one or two molten terne baths then into palm oil. The coatings are designated in terms of lb. per double base box, a double base box consisting of 112 sheets 20 x 28 in. The range of coatings varies from 12-40 lb. on this basis. Some indication of the thickness of coating may be noted by the size of the spangle or mottle. This decreases with an increase in coating thickness if the conditions of manufacture are similar. The size of mottle may be varied, however, by changing the rate of cooling.

Long ternes are machine coated sheets of comparatively large size. The sheets are frequently made in galvanizing rather than tinning mills and are similar to galvanized sheet in size. As with thinly coated terne plate, the base metal is passed through a zinc chloride or zinc ammonium chloride flux, through a terne

metal bath, and through a palm oil finishing compartment, by machine. The coating obtained is normally 8 lb. per double base box or under.
